US 2024/0073068 A1 Feb. 29, 2024

An apparatus is disclosed that implements interference and/or clutter cancellation using cross-channel equalization. In example aspects, the apparatus includes a wireless transceiver configured to be connected to multiple feed ports. The wireless transceiver is also configured to transmit an electromagnetic signal using a first feed port of the multiple feed ports. A modulated spur is generated based on the transmission of the electromagnetic signal. The wireless transceiver is additionally configured to receive two versions of a receive signal respectively via two feed ports of the multiple feed ports. The receive signal comprises the modulated spur and a mutual-coupling component associated with the transmission of the electromagnetic signal. The wireless transceiver is further configured to generate a filtered signal by attenuating the mutual-coupling component and the modulated spur within one of the two versions of the receive signal using cross-channel equalization.

## CROSS-REFERENCE TO RELATED APPLICATION(S)

This application claims the benefit of U.S. Provisional Application No. 63/373,838, filed 29 Aug. 2022, the disclosure of which is hereby incorporated by reference in its entirety herein.

## TECHNICAL FIELD

This disclosure relates generally to wireless transceivers and, more specifically, to attenuating self-made interference and/or environmental clutter within a receiver.

## BACKGROUND

To increase transmission rates and throughput, cellular and other wireless networks are using signals with higher frequencies and smaller wavelengths. As an example, 5<sup>th</sup>-generation (5G)-capable devices communicate with networks using frequencies that include those at or near the extremely-high frequency (EHF) spectrum (e.g., frequencies greater than 25 gigahertz (GHz)) with wavelengths at or near millimeter wavelengths. These signals have various technological challenges, such as higher path loss as compared to signals for earlier generations of wireless communications. In certain scenarios it can be difficult for a 5G wireless signal to travel far enough to make cellular communications feasible at these higher frequencies.

Transmit power levels can be increased or beamforming can concentrate energy in a particular direction to compensate for the higher path loss. These types of compensation techniques, however, increase power densities. The Federal Communications Commission (FCC) has determined a maximum permitted exposure (MPE) limit to accommodate these higher power densities. To meet targeted guidelines based on this MPE limit, devices balance performance with transmission power and other considerations. This balancing act can be challenging to realize given cost, size, functional design objectives and/or involved constraints.

## SUMMARY

An apparatus is disclosed that implements interference and/or clutter cancellation using cross-channel equalization. In example implementations, a computing device employs proximity detection to detect nearby objects and adjusts transmission parameters for wireless communication based on relative positions of these objects. The computing device includes an interference and clutter cancellation module to attenuate or suppress self-made interference and/or environmental clutter. The self-made interference can include slow time-varying mutual coupling between antennas and/or fast time-varying modulated spurs generated during proximity detection. The environmental clutter represents another type of slow time-varying signal component. To attenuate the interference and/or clutter, the interference and clutter cancellation module employs cross-channel equalization, which equalizes the slow time-varying components across at least two channels of a receiver. After cross-channel equalization, one of the channels is used as a reference to cancel the slow time-varying component and/or fast time-varying component that is present within the other channel. This cancella-

2

tion enables detection of weak reflections to be processed for proximity detection and a desired false-alarm rate to be realized.

In an example aspect, an apparatus is disclosed. The apparatus includes a wireless transceiver configured to be connected to multiple feed ports. The wireless transceiver is configured to transmit an electromagnetic signal using a first feed port of the multiple feed ports. A modulated spur is generated based on the transmission of the electromagnetic signal. The wireless transceiver is also configured to receive two versions of a receive signal respectively via two feed ports of the multiple feed ports. The receive signal comprises a mutual-coupling component associated with the transmission of the electromagnetic signal and the modulated spur. The wireless transceiver is additionally configured to generate a filtered signal by attenuating the mutual-coupling component and the modulated spur within one of the two versions of the receive signal using cross-channel equalization.

In an example aspect, an apparatus is disclosed. The apparatus includes means for transmitting an electromagnetic signal using a first feed port of multiple feed ports. A modulated spur is generated based on the transmission of the electromagnetic signal. The apparatus also includes means for receiving two versions of a receive signal respectively via two feed ports of the multiple feed ports. The receive signal comprises the modulated spur and a mutual-coupling component associated with the transmission of the electromagnetic signal. The apparatus additionally includes means for generating a filtered signal by attenuating the mutual-coupling component and the modulated spur within one of the two versions of the receive signal using cross-channel equalization.

In an example aspect, a method for interference and/or clutter cancellation using cross-channel equalization is disclosed. The method includes transmitting an electromagnetic signal using a first feed port of multiple feed ports. A modulated spur is generated based on the transmission of the electromagnetic signal. The method also includes receiving two versions of a receive signal respectively via two feed ports of the multiple feed ports. The receive signal comprises the modulated spur and a mutual-coupling component associated with the transmission of the electromagnetic signal. The method additionally includes generating a filtered signal by attenuating the mutual-coupling component and the modulated spur within one of the two versions of the receive signal using cross-channel equalization.

In an example aspect, an apparatus is disclosed. The apparatus includes a wireless transceiver configured to be connected to multiple feed ports. The wireless transceiver is configured to transmit an electromagnetic signal using a first feed port of the multiple feed ports. A modulated spur is generated based on the transmission of the electromagnetic signal. The modulated spur comprises a fast time-varying component having a magnitude or phase that varies substantially within a duration of a pulse of the electromagnetic signal. The wireless transceiver is also configured to receive two versions of a receive signal respectively via two feed ports of the multiple feed ports. The receive signal comprises the modulated spur. The wireless transceiver is further configured to satisfy a target false-alarm rate in the presence of the modulated spur.

## BRIEF DESCRIPTION OF DRAWINGS

FIG. 1 illustrates an example operating environment for interference and/or clutter cancellation using cross-channel equalization.

3

FIG. 2-1 illustrates an example operating environment for performing proximity detection using cross-channel equalization.

FIG. 2-2 illustrates another example operating environment for performing proximity detection using cross-channel equalization.

FIG. 3 illustrates an example sequence flow diagram for proximity detection using cross-channel equalization.

FIG. 4 illustrates multiple examples of an antenna for interference and/or clutter cancellation using cross-channel equalization.

FIG. 5 illustrates examples of a wireless transceiver, an interference and clutter cancellation module, and a modem for interference and/or clutter cancellation using cross-channel equalization.

FIG. 6 illustrates an example local oscillator circuit for supporting proximity detection and wireless communication.

FIG. 7 illustrates an example plot of a receive signal for interference and clutter cancellation using cross-channel equalization.

FIG. 8 illustrates an example implementation of an interference and clutter cancellation module for interference and/or clutter cancellation using cross-channel equalization.

FIG. 9 is a flow diagram illustrating an example process for interference and/or clutter cancellation using cross-channel equalization.

#### DETAILED DESCRIPTION

Current high-frequency and small-wavelength communications balance performance with a need to meet the Federal Communications Commission's maximum permitted exposure limit (e.g., the FCC's MPE limit). Inefficient balancing can prevent devices from taking full advantage of increased data rates (e.g., those enabled by 5G wireless communications). Because exposure is affected by a proximity of a user to a device's antenna, however, techniques described in this document enable greater wireless performance while staying within the FCC's MPE limit. To do so, these techniques detect a user's proximity to a device. Based on the detected proximity, the device can balance a power density of transmitted wireless signals with the requirement to meet the MPE limit. As a result, the device is permitted to transmit wireless signals with higher average power levels, which enables the wireless signals to travel farther, such as between a smart phone and a remote cellular base station. Devices and techniques described herein may additionally or alternatively be used to comply with radio frequency exposure requirements promulgated by an organization or jurisdiction outside of the United States.

Some proximity-detection techniques may use a dedicated sensor to detect the user, such as a camera or an infrared sensor. However, these sensors may be bulky or expensive. Furthermore, a single electronic device can include multiple antennas that are positioned on different surfaces (e.g., on a top, a bottom, or opposite sides). To account for each of these antennas, multiple cameras or sensors may need to be installed near each of these antennas, which further increases a cost and size of the electronic device.

In contrast, techniques for proximity detection with interference and/or clutter cancellation using cross-channel equalization are described herein. The described techniques utilize a wireless transceiver and antennas within a computing device to perform proximity detection and optionally determine a relative position of an object (e.g., a range

4

and/or angle to the object). With proximity detection, a transmission parameter that is used for wireless communication can be adjusted to enable the wireless transceiver to meet guidelines promulgated by the government or the wireless industry, such as a Maximum Permitted Exposure (MPE) limit as determined by the Federal Communications Commission (FCC). Furthermore, by actively detecting an object's relative position, a surrounding environment can be continually monitored and the transmission parameter can be incrementally adjusted to account for movement by the object while achieving a desired false-alarm rate. Additionally, devices and techniques described herein may additionally or alternatively be used for or modified for purposes other than exposure compliance, for example to detect objects other than a user, to map an environment, for other forms of radio frequency (RF) or millimeter-wave (mmW) sensing, for sensor assisted communication or joint communicating and sensing, etc.

Due to a proximity of the antennas with respect to each other, the antennas can be mutually coupled such that energy leaks between a transmitting antenna and a receiving antenna. During proximity detection, this mutual coupling can raise a noise floor of the wireless transceiver and make it challenging to detect objects. The wireless transceiver can also receive modulated spurs (or modulated spurious signals), which are generated by the wireless transceiver during transmission. Additionally or alternatively, the wireless transceiver can receive reflections of clutter within an external environment. During proximity detection, the computing device can incorrectly identify the modulated spur and/or environmental clutter as an object-of-interest, which can degrade the false-alarm-rate performance of the computing device.

To detect the object in the presence of this self-made interference and/or environmental clutter, an interference and clutter cancellation module of the computing device processes at least two receive signals in such a way as to suppress or attenuate slow time-varying components (e.g., the mutual coupling or environmental clutter) and/or fast time-varying components (e.g., the modulated spurs) within at least one of the two receive signals. The at least two receive signals can be obtained from at least two feed ports that are associated with a same antenna or different antennas. To attenuate the interference and/or clutter, the interference and clutter cancellation module employs cross-channel equalization, which equalizes the slow time-varying components across the at least two receive signals. After cross-channel equalization, one of the equalized receive signals is used as a reference to cancel the slow time-varying component and/or fast time-varying component within the other equalized receive signal. This cancellation enables detection of weak reflections to be processed for proximity detection and enables the computing device to realize a desired false-alarm rate.

Some embodiments may offer a relatively inexpensive approach that can utilize existing transceiver hardware and antennas. The interference and clutter cancellation module may marginally impact a design of the wireless transceiver and can be implemented in software or hardware. The described techniques need not utilize a calibration procedure or training sequence (e.g., those involving a characterization of a mutual coupling channel, a modulated spur, or clutter). Instead, estimations of the interference and/or environmental clutter is made in real-time, thereby enabling responsive adaptation to various changes, including changes in antenna impedance (e.g., changes in a proximity of a user's hand to an antenna), antenna load variations (e.g., changes in solar

loading), or changes in the environment. With this adaptive capability, proximity detection can be performed using a variety of different antenna designs or antenna array configurations.

In some implementations, the computing device may be utilized in stand-alone proximity-detection applications. For example, the computing device can be implemented as an automotive bumper sensor to assist with parking or autonomous driving. As another example, the computing device can be installed on a drone to provide collision avoidance. In other implementations, the computing device can selectively perform proximity detection or wireless communication. In such cases, dual-use of components within the wireless transceiver of a computing device may be enabled, which decreases cost and size of the wireless transceiver, as well as the computing device. Based on the proximity detection, and as described herein, transmission parameters can be adjusted for wireless communication to enable the wireless transceiver to meet safety guidelines promulgated by the government or the wireless industry, such as the MPE limit as determined by the FCC.

FIG. 1 illustrates an example environment 100 for interference and clutter cancellation using cross-channel equalization. In the environment 100, a computing device 102 communicates with a base station 104 through a wireless communication link 106 (wireless link 106). In this example, the computing device 102 is depicted as a smartphone. However, the computing device 102 can be implemented as any suitable computing or electronic device, such as a modem, a cellular base station, a broadband router, an access point, a cellular phone, customer premises equipment (CPE), a gaming device, a navigation device, a media device, a laptop computer, a desktop computer, a tablet computer, a wearable computer, a server, a network-attached storage (NAS) device, a smart appliance or other internet of things (IoT) device, a medical device, a vehicle-based communication system, a radar, a radio apparatus, and so forth.

The base station 104 communicates with the computing device 102 via the wireless link 106, which can be implemented as any suitable type of wireless link. Although depicted as a tower of a cellular network, the base station 104 can represent or be implemented as another device, such as a satellite, a server device, a terrestrial television broadcast tower, an access point, a peer-to-peer device, another smartphone, a mesh network node, and so forth. Therefore, the computing device 102 may communicate with the base station 104 or another device via a wireless connection.

The wireless link 106 can include a downlink of data or control information communicated from the base station 104 to the computing device 102, an uplink of other data or control information communicated from the computing device 102 to the base station 104, or both a downlink and an uplink. The wireless link 106 can be implemented using any suitable communication protocol or standard, such as 2<sup>nd</sup>-generation (2G), 3<sup>rd</sup>-generation (3G), 4<sup>th</sup>-generation (4G), or 5<sup>th</sup>-generation (5G) cellular; IEEE 802.11 (e.g., Wi-Fi®); IEEE 802.15 (e.g., Bluetooth® or UWB); IEEE 802.16 (e.g., WiMAX®); and so forth. In some implementations, the wireless link 106 may wirelessly provide power and the base station 104 or the computing device 102 may comprise a power source.

As shown, the computing device 102 includes an application processor 108 and a computer-readable storage medium 110 (CRM 110). The application processor 108 can include any type of processor, such as a multi-core processor, that executes processor-executable code stored by the

CRM 110. The CRM 110 can include any suitable type of data storage media, such as volatile memory (e.g., random access memory (RAM)), non-volatile memory (e.g., Flash memory), optical media, magnetic media (e.g., disk), and so forth. In the context of this disclosure, the CRM 110 is implemented to store instructions 112, data 114, and other information of the computing device 102, and thus does not include transitory propagating signals or carrier waves.

The computing device 102 can also include input/output ports 116 (I/O ports 116) and a display 118. The I/O ports 116 enable data exchanges or interaction with other devices, networks, or users. The I/O ports 116 can include serial ports (e.g., universal serial bus (USB) ports), parallel ports, audio ports, infrared (IR) ports, user interface ports such as a sensing portion of a touchscreen, and so forth. The display 118 presents graphics of the computing device 102, such as a user interface associated with an operating system, program, or application. Alternatively or additionally, the display 118 can be implemented as a display port or virtual interface, through which graphical content of the computing device 102 is presented, and/or the display 118 can be omitted.

A wireless transceiver 120 of the computing device 102 provides connectivity to respective networks and other electronic devices connected therewith. The wireless transceiver 120 can facilitate communication over any suitable type of wireless network, such as a wireless local area network (WLAN), peer-to-peer (P2P) network, mesh network, cellular network, ultra-wideband (UWB) network, wireless wide-area-network (WWAN), and/or wireless personal-area-network (WPAN). In the context of the example environment 100, the wireless transceiver 120 enables the computing device 102 to communicate with the base station 104 and networks connected therewith. However, the wireless transceiver 120 can also enable the computing device 102 to communicate “directly” with other devices or networks.

The wireless transceiver 120 includes circuitry and logic for transmitting and receiving signals via an antenna 122. Components of the wireless transceiver 120 can include amplifiers, switches, mixers, analog-to-digital converters, digital-to-analog converters, filters, and so forth for conditioning signals (e.g., for generating or processing signals). The wireless transceiver 120 can also include logic to perform in-phase/quadrature (I/Q) operations, such as synthesis, encoding, modulation, decoding, demodulation, and so forth. In some cases, components of the wireless transceiver 120 are implemented as separate transmitter and receiver entities. Additionally or alternatively, the wireless transceiver 120 can be realized using multiple or different sections to implement respective transmitting and receiving operations (e.g., separate transmit and receive chains). In general, the wireless transceiver 120 processes data and/or signals associated with communicating data of the computing device 102 over the antenna 122 and/or processes signals associated with proximity detection.

In the example shown in FIG. 1, the computing device 102 includes at least one interference and clutter cancellation module 124 and at least one modem 126. The interference and clutter cancellation module 124 can be a separate module or integrated within the wireless transceiver 120 and/or the modem 126. In general, the interference and clutter cancellation module 124 can be incorporated in or realized using software, firmware, hardware, fixed logic circuitry, or combinations thereof. The interference and clutter cancellation module 124 can be implemented within an integrated circuit or as part of the modem 126 or other electronic component of the computing device 102. In some

implementations, the modem **126** may execute computer-executable instructions that are stored within the CRM **110** to implement the interference and clutter cancellation module **124**.

In operation, the interference and clutter cancellation module **124** can cancel self-made interference (e.g., interference due to mutual coupling or modulated spurs) as well as environmental clutter to enable detection of relatively weak signal components that are analyzed for proximity detection. Attenuating the self-made interference and environmental clutter also enables the computing device **102** to operate within a target false-alarm rate. To achieve this, the interference and clutter cancellation module **124** implements an adaptive scheme that can estimate both slow time-varying components and fast time-varying components for subsequent cancellation. The slow time-varying components vary detectably in magnitude and/or phase across successive pulses (e.g., across an inter-pulse period (IPP) of an electromagnetic signal **226**). The fast time-varying components vary detectably in magnitude and/or phase within each pulse (e.g., across a duration of each pulse of the electromagnetic signal **226**). In comparison, the fast time-varying components vary appreciably more in magnitude and/or phase relative to the slow time-varying components across a given pulse (or during a given pulse). The amount of variation in magnitude or phase can be approximately 5% or more (e.g., approximately 10%, 20%, 50% or more) of a median value for a given time frame.

The interference and clutter cancellation module **124** includes at least one cross-channel equalizer **128** (x-channel equalizer **128**), which can at least partially implement cross-channel equalization. In particular, the cross-channel equalizer equalizes the slow time-varying components across at least two receive channels. This equalization enables the interference and clutter cancellation module **124** to use one of the receive channels as a reference channel to cancel the slow time-varying component and/or fast time-varying component from the other receive channel. By cancelling these components, the interference and clutter cancellation module **124** reduces a likelihood of the computing device **102** making false detections, particularly false detections based on the slow time-varying component and/or the fast time-varying component. As a result, the computing device **102** can satisfy a target false-alarm-rate performance in the presence of mutual coupling, a modulated spur, and/or clutter. The computing device **102** satisfies a target false-alarm-rate performance by declaring fewer false alarms within a set amount of time compared to a false-alarm-rate threshold.

The modem **126**, which can be implemented as a processor, controls the wireless transceiver **120** and enables proximity detection **130** or wireless communication **132** to be performed. The modem **126** can include a portion of the CRM **110** or can access the CRM **110** to obtain computer-readable instructions. The modem **126** can include baseband circuitry to perform high rate sampling processes that can include analog-to-digital conversion, digital-to-analog conversion, Fourier transforms, gain correction, skew correction, frequency translation, and so forth. The modem **126** can provide communication data to the wireless transceiver **120** for transmission. The modem **126** can also process a baseband version of a signal obtained from the wireless transceiver **120** to generate data, which can be provided to other parts of the computing device **102** via a communication interface for proximity detection **130** or wireless communication **132**.

The computing device **102** can also include a controller (not separately shown), e.g., to realize the interference and clutter cancellation module **124**. The controller can include at least one processor and CRM, which stores computer-executable instructions (such as the application processor **108**, the CRM **110**, and the instructions **112**). The processor and the CRM can be localized at one module or one integrated circuit chip or can be distributed across multiple modules or chips. Together, a processor and associated instructions can be realized in separate circuitry, fixed logic circuitry, hard-coded logic, and so forth. The controller can be implemented as part of the wireless transceiver **120**, the modem **126**, the application processor **108**, a special-purpose processor configured to perform MPE techniques, a general-purpose processor, some combination thereof, and so forth.

In an example implementation, the wireless transceiver **120** supports proximity detection **130** and wireless communication **132**. In other words, the wireless transceiver **120** can be configured to perform proximity detection **130** during a first time interval and perform wireless communication **132** during a second time interval. In other example implementations, the wireless transceiver **120** supports proximity detection **130** and does not support wireless communication **132**. In this case, the wireless transceiver **120** can be a transceiver of a dedicated radar system, which is integrated within the computing device **102** or a stand-alone radar system. In still other example implementations, the wireless transceiver **120** supports other applications, which can benefit from aspects of interference and/or clutter cancellation using cross-channel equalization. In other examples, separate transceivers are respectively configured for proximity detection **130** and wireless communication **132**.

FIG. 2-1 illustrates an example operating environment **200-1** for proximity detection **130**. In the example environment **200-1**, a hand **214** of a user holds the computing device **102**. In one aspect, the computing device **102** communicates with the base station **104** by transmitting an uplink signal **202** (UL signal **202**) or receiving a downlink signal **204** (DL signal **204**) via the two or more antennas **122**. A user's thumb, however, can represent a proximate object **206** that may be exposed to radiation via the uplink signal **202**. Other situations are also possible in which the user represents the proximate object **206**, including those in which the user is near the computing device **102** but not physically touching the computing device **102**, as later shown in FIG. 2-2.

To detect whether the object **206** exists or is within a detectable range, the computing device **102** generally transmits an electromagnetic (EM) signal **226** (EM signal **226**) via at least one of the antennas **122**. In a near field, the electromagnetic signal **226** can be referred to as an electromagnetic (EM) field **208**. In a far field, the electromagnetic signal **226** can be referred to as a radar transmit signal (not shown in FIG. 2-1). In some cases, the electromagnetic signal **226** may be generated such that it includes a single frequency or tone or multiple frequencies or tones. For example, the electromagnetic signal **226** can include a frequency-modulated continuous wave (FMCW) signal (e.g., a linear frequency-modulated (LFM) continuous wave signal or chirp signal, a triangular frequency-modulated continuous wave signal, a sawtooth frequency-modulated continuous wave signal, and so forth).

The antennas **122** may be arranged via modules and/or arrays and may have a variety of configurations. For example, the antennas **122** may comprise at least two different antennas, at least two antenna elements **212** of an antenna array **216** (as shown towards the bottom of FIG.

2-1), at least two antenna elements **212** associated with different antenna arrays **216**, or any combination thereof. The antenna array **216** is shown to include multiple antenna elements **212-1** to **212-N**, where N represents a positive integer greater than one. Further, the array **216** may be a multi-dimensional array. Additionally or alternatively, the antenna array **216** may be configured for beam management techniques, such as beam determination, beam measurement, beam reporting, or beam sweeping. A distance between the antenna elements **212** in the antenna array **216** can be based on frequencies that the wireless transceiver **120** emits. For example, the antenna elements **212** in the antenna array **216** can be spaced by approximately half a wavelength from each other (e.g., by approximately half a centimeter apart for frequencies around 30 GHz). The antennas **122** may be implemented using any type of antenna, including patch antennas, dipole antennas, bowtie antennas, or a combination thereof, as further described with respect to FIG. 4.

An example near-field case is further illustrated at the bottom left of FIG. 2-1. Here, an amplitude of the electromagnetic field **208** is illustrated with different shades of grey, where darker shades represent higher amplitudes and lighter shades represent lower amplitudes. If the object **206** is proximate to one of the antenna elements **212** (e.g., one of the antennas **122**), interactions of the object **206** with the electromagnetic field **208** produce one or more perturbations (e.g., disturbances or changes) in the electromagnetic field **208**, such as perturbation **210**. The perturbation **210** represents a variation in a magnitude or phase of the electromagnetic field **208** due to the object **206** causing different constructive or destructive patterns to occur within the electromagnetic field **208**. In some implementations, the electromagnetic field **208** is configured such that objects **206** within approximately five centimeters (cm) can be detected, including objects within three or four centimeters. For some frequencies of the electromagnetic field **208**, this distance can be associated with a near-field region.

In the depicted example, a first antenna element **212-1** emits the electromagnetic field **208**, and a second antenna element **212-2** senses the perturbation **210** for proximity detection **130**. The second antenna element **212-2** may be co-located with respect to the first antenna element **212-1** as part of the antenna array **216** or otherwise proximate to the first antenna element **212-1**. In some cases, the second antenna element **212-2** is adjacent to the first antenna element **212-1** within a same antenna array **216** (e.g., there are no antenna elements **212** physically located between the first antenna element **212-1** and the second antenna element **212-2**). The same antennas **122** or a subset of the same antennas **122** used to communicate with the base station **104** can be used for proximity detection **130**. In other examples, one or more of the antennas **122** used for proximity detection **130** are not used for communicating with the base station **104**.

A response of the second antenna element **212-2** to the electromagnetic field **208** is affected by the object **206** reflecting or absorbing the electromagnetic field **208** and also by any mutual coupling or interference. This interference is represented by interference signal **218**, which can include a mutual-coupling component **220** (MC component **220**), a modulated spur **222** (mod. spur **222**), and/or a clutter component **224**.

The mutual-coupling component **220** represents energy that leaks between a transmitting antenna **122** and a receiving antenna **122** during proximity detection **130**. A magnitude and phase of the mutual-coupling component **220** can

vary slowly across each pulse of the electromagnetic signal **226** (e.g., across each pulse of the electromagnetic field **208** or the radar transmit signal). As such, the mutual-coupling component **220** can be referred to as a slow time-varying component. Variations in the mutual-coupling component **220** can be caused, at least in part, by changes in antenna impedance or load variations. For example, such variations can occur due to a proximity of the user's hand **214** to the antennas **122**, solar loading, or temperature fluctuations.

The modulated spur **222** represents a spurious signal that is generated based on the transmission of the electromagnetic signal **226** (e.g., based on the transmission of the electromagnetic field **208** or the radar transmit signal) and is modulated in frequency similar to the electromagnetic signal **226**. The modulated spur **222** can be inherently produced by components within the wireless transceiver **120** that have realistic (e.g., non-ideal) performance characteristics. Example components that can produce a spur include amplifiers and mixers. In comparison to the mutual-coupling component **220**, a magnitude and/or phase of the modulated spur **222** can vary quickly across each pulse of the electromagnetic signal **226**. In other words, a frequency of the modulated spur **222** can be substantially higher than a frequency of the mutual-coupling component **220**. The modulated spur **222** can be referred to as a fast time-varying component.

The mutual-coupling component **220** and the modulated spur **222** can be co-linear due to their relationship to a common transmitter (e.g., because they are associated with a same transmit path). This means that the mutual-coupling component **220** and the modulated spur **222** present within one receive channel can be related to the mutual-coupling component **220** and the modulated spur **222** that is present within another receive channel by a scaling factor.

The clutter component **224** represents a portion of the electromagnetic signal **226** (e.g., the electromagnetic field **208** or the radar transmit signal) that is reflected by environmental clutter. The environmental clutter can include an object that exists outside of the computing device **102** or a component that is internal to the computing device **102**, such as a housing of the computing device **102**. In many situations, the clutter is stationary and/or present at close ranges to the antennas **122**. The clutter component **224** can have a magnitude and phase that vary slowly across each pulse of the electromagnetic signal **226**. As such, the clutter component **224** can be referred to as a slow time-varying component. The mutual-coupling component **220**, the modulated spur **222**, and the clutter component **224** are further described with respect to FIG. 6.

In some implementations, the wireless transceiver **120** can generate the electromagnetic signal **226** via the first antenna element **212-1** during a same time that the second antenna element **212-2** is used to receive a version of the electromagnetic signal **226** (e.g., to sense the electromagnetic field **208** or receive a reflected version of the radar transmit signal). In the near-field case, energy from the electromagnetic field **208** induces a current in the second antenna element **212-2**, which is used to measure the perturbation **210** or the resulting electromagnetic field **208** that is disturbed by the object **206**. By sensing the perturbation **210**, a determination can be made as to whether the object **206** is present or outside a detectable range (e.g., not present). The detectable range may be within approximately 5 cm from the antennas **122**, between 0 and 4 cm from the antennas **122**, and so forth.

In the far-field case, the second antenna element **212-2** receives a version of the radar transmit signal that is

## 11

reflected by the object 206. This reflected version of the radar transmit signal is referred to as a radar receive signal. The radar receive signal can have a different phase and/or frequency relative to the radar transmit signal and the interference signal 218 based on reflection properties and/or motion of the object 206. In general, the radar receive signal contains information that can be used for detecting the object 206 and for determining a range to the object 206.

In general, the detectable range can vary based on transmission power or sensitivity of the wireless transceiver 120. A duration for which the electromagnetic signal 226 is generated can also be based on the detectable range. Example durations can range from approximately one microsecond to several tens of microseconds.

In the far-field case, the detectable range can include ranges that can be readily measured using radar-based techniques. In the near-field case, however, the detectable range can include ranges that are not readily measured using radar-based techniques. For example, the radar-based techniques can be limited to ranges that are farther than a minimum range, which is proportional to a bandwidth of the FMCW signal. Example minimum ranges include 4 cm or 2 cm for a FMCW signal having a bandwidth of 4 GHz or 8 GHz, respectively. Therefore, to detect closer distances using radar-based techniques, the wireless transceiver 120 generates larger bandwidth signals at an expense of increased design complexity or increased cost of the wireless transceiver 120. Using the described techniques, however, the range to the object 206 can be measured at distances closer than these minimum ranges. In this way, the described techniques can be used to augment close-range detection even if radar-based techniques are used for far-range detection.

A propagation distance between the antenna element 212 and the object 206 and a partial absorption of the electromagnetic signal 226 via the object 206 may cause the received signal (e.g., the sensed perturbation 210 or the radar receive signal) to be weaker relative to the interference signal 218. In general, responses of the receiving antennas 122 contain information that can be used for detecting the object 206 and optionally determining a relative position of the object 206 (e.g., determining a range and/or angle to the object 206).

In one aspect, the interference signal 218 can exist within the responses of the receiving antennas 122 due to a direct or indirect coupling between the transmitting antenna 122 and the receiving antennas 122 (e.g., the antennas 122 are mutually coupled). In the depicted configuration, the antennas 122 are co-located or otherwise proximate to one another. Due to this proximity, the antennas 122 are mutually coupled electromagnetically such that a portion of the energy that is radiated via one of the antennas 122 generates interference that makes it challenging to detect the object 206 (assuming the object 206 is present). In another aspect, the interference signal 218 additionally or alternatively exists within the response due to a direct or indirect coupling between a transmitter, which generates the electromagnetic signal 226, and a receiver, which receives the antenna response.

In some cases, the interference signal 218 is significantly stronger in magnitude than a portion of a received signal that is associated with the object 206 (e.g., a portion of the receive signal that is associated with the perturbation 210 or the radar receive signal). As such, the interference signal 218 can prevent the computing device 102 from detecting the object 206, absent implementation of a technique to cancel (e.g., attenuate or suppress) the interference signal 218. For

## 12

example, the portion of the receive signal that is associated with the object 206 can be obscured by sidelobes of the interference signal 218. The interference and clutter cancellation module 124, however, attenuates the interference signal 218 to enable the object 206 to be detected (if present) in the presence of mutual coupling 220, modulated spurs 222, and/or environmental clutter 224. This attenuation also enables the computing device 102 to avoid false detections, including in situations in which the object 206 is not present. Based on the proximity detection 130, a transmission parameter can be adjusted for use during wireless communication 132.

FIG. 2-2 illustrates another example operating environment 200-2 for performing proximity detection 130. In contrast to the environment 200-1 of FIG. 2-2, the computing device 102 is not held by the user in environment 200-2. In the example environment 200-2, the computing device 102 is positioned on a table 228 (or more generally a surface) and is within arm's reach to the user. Other situations are also possible, such as the computing device 102 being propped up on a table and the user watching a video on the computing device 102 from a distance.

As the user moves around within a proximity of the computing device 102, their hand 214 can move into a detectable range, as indicated at 230. By performing proximity detection 130 with cross-channel equalization, the computing device 102 can detect the user's hand 214 and attenuate any interference signals 218. An example sequence of the computing device 102 switching between proximity detection 130 and wireless communication 132 is further described with respect to FIG. 3.

FIG. 3 illustrates an example sequence flow diagram for proximity detection 130, with time elapsing in a downward direction. Examples of a wireless communication mode are shown at 302 and 306, and examples of a proximity detection mode are shown at 304 and 308. The proximity detection mode can occur at fixed time intervals, between active data cycles that occur during wireless communication 132, at predetermined times as set by the modem 126, as part of an initialization process before wireless communications 132 occur, responsive to detection of device movement, or based on indications that the user may be proximate to the device (e.g., based on the wireless transceiver 120 observing a decrease in power in a downlink signal 204 or the application processor 108 determining that the user is interacting with the display 118 of the computing device 102), etc.

At 302, the wireless transceiver 120 transmits a high-power (e.g., normal) uplink signal 202-1 configured to provide sufficient range to a destination, such as a base station 104. After transmitting the uplink signal 202-1, the electromagnetic signal 226-1 (or proximity detection signal) is transmitted via the wireless transceiver 120 and the antennas 122 at 304. As described above, the electromagnetic signal 226 enables the computing device 102 to detect an object 206 and determine if the object 206 is near the computing device 102. In this case, the electromagnetic signal 226-1 is represented by a low-power wide-band signal. Based on a detection, the wireless transceiver 120 can adjust a transmission parameter for a next uplink signal 202 to account for MPE compliance guidelines.

The proximity detection mode can also determine the range to the object 206 in some examples, thereby enabling transmission of the uplink signal 202 to comply with range-dependent guidelines, such as a maximum power density. Because power density is proportional to transmit power and inversely proportional to range, an object 206 at a closer

13

range is exposed to a higher power density than another object **206** at a farther range for a same transmit power level. Therefore, a similar power density at the object **206** can be achieved by increasing the transmit power level if the object **206** is at a farther range and decreasing the transmit power level if the object **206** is at a closer range. In this way, the wireless transceiver **120** can adjust transmission of the uplink signal **202** to enable the power density at the object **206** for both the closer range and the farther range to be below the maximum power density. At the same time, because the range is known, the transmit power level can be increased to a level that facilitates wireless communication **132** and comports with the compliance guideline.

At **306**, the wireless transceiver **120** transmits a next uplink signal **202**. In the depicted example, a high-power uplink signal **202-2** is transmitted if an object **206** is not detected. Alternatively, a low-power uplink signal **202-3** is transmitted if the object **206** is detected. The low transmit power can be, for example, between approximately five and twenty decibel-milliwatts (dBm) less than the high-power signal at **302**. In addition to or instead of changing a power of the next uplink signal **202**, the uplink signal **202** can be transmitted using a different antenna within the computing device **102** or using a different beam steering angle (e.g., different than the antennas **122** or the beam steering angle used for transmitting the uplink signal **202-1** at **302**). Although not shown, the wireless transceiver **120** can alternatively skip the wireless communication mode at **306** and perform another proximity detection mode using another antenna **122** or a different transmit power level to detect objects **206** at various locations or distances around the computing device **102**. While certain operations were described above based on a range to the object **206**, it will be appreciated that operations in the wireless communication mode at **306** or adjustments made pursuant to the proximity detection mode at **304** may be based merely upon whether the object **206** is present or not, irrespective of the range thereto.

At **308**, the wireless transceiver **120** and antennas **122** transmit another electromagnetic signal **226-2** (e.g., another proximity detection signal) to attempt to detect the object **206**. By scheduling multiple proximity detection modes over some time period, transmission of the uplink signal **202** can be dynamically adjusted based on a changing environment or movement by the object **206**. Furthermore, appropriate adjustments can be made to balance communication performance with compliance or radiation requirements.

The sequence described above can also be applied to other antennas. The other antennas and the antennas **122** may transmit multiple electromagnetic signals **226** sequentially or in parallel. To enable proximity detection **130** in the presence of self-made interference and/or environmental clutter, the wireless transceiver **120** receives antenna responses via at least two feed ports, which are further described with respect to FIG. 4.

FIG. 4 illustrates an example antenna **122** for interference and/or clutter cancellation using cross-channel equalization and three example implementations thereof. The example antenna **122** illustrated in FIG. 4 can be used to implement either of the antennas **122** (e.g., a transmitting antenna or a receiving antenna). In general, the antenna **122** in FIG. 4 is described with respect to a receiving antenna **122**. In the depicted configuration (in the top half of FIG. 4), the antenna **122** includes multiple feed ports **402**, such as a first feed port **402-1** and a second feed port **402-2**. The response of the antenna **122** to the electromagnetic signal **226** is separated into multiple versions **404**, such as versions **404-1** and **404-2**

14

respectively obtained via the feed ports **402-1** and **402-2**. Although similar, the multiple versions **404** of the antenna response vary due to differences in a type of feed port **402** or differences due to location or orientation of the feed ports **402-1** and **402-2**. These versions **404-1** and **404-2** are used by the interference and clutter cancellation module **124** to perform cross-channel equalization **406**, which is further described with respect to FIG. 8.

Three example types of antenna **122** are depicted towards the bottom of FIG. 4. In one example, the antenna **122** comprises a dipole antenna **408**, which includes a pair of differential feed ports **410** (e.g., a positive (+) feed port **410-1** and a negative (−) feed port **410-2**). Thus, the feed ports **402-1** and **402-2** can be implemented using the differential feed ports **410-1** and **410-2** such that the versions **404-1** and **404-2** are out-of-phase with respect to each other (e.g., differ in phase by approximately 180 degrees). As another example, the antenna **122** comprises a patch antenna **412**, which includes a horizontally-polarized feed port **414-1** and a vertically-polarized feed port **414-2**. Accordingly, the versions **404-1** and **404-2** have orthogonal polarities if the feed ports **402-1** and **402-2** are implemented using the polarized feed ports **414**. In this instance, the versions **404-1** and **404-2** respectively represent a horizontally-polarized version and a vertically-polarized version, but diagonal or other polarizations may be implemented. As yet another example, the antenna **122** comprises a bowtie antenna **416**, which includes directional feed ports **418-1** and **418-2**. In this case, the versions **404-1** and **404-2** represent different angular directions that are sensed along different angles of arrival.

In FIG. 4, the feed ports **402** and the versions **404** of the antenna responses are shown to be associated with the antenna **122**. Alternatively, the feed ports **402** and the versions **404** may be obtained using two different antennas **122**. In some implementations, the interference and clutter cancellation module **124** accepts versions **404** of the antenna response that are each associated with multiple antennas **122**.

Consider a case in which the wireless transceiver **120** performs analog or hybrid beamforming. In this case, beamforming circuitry (not shown) is coupled between the feed ports **402** and the interference and clutter cancellation module **124**. During operation, the beamforming circuitry combines corresponding versions **404** of the antenna responses across multiple antennas **122**. For example, the beamforming circuitry combines versions **404-1** of the antenna responses between two or more antennas **122** by coupling the feed ports **402-1** of the two or more antennas **122** together. Also, the beamforming circuitry combines versions **404-2** of the antenna responses between the two or more antennas **122** by coupling the feed ports **402-2** of the two or more antennas **122** together. In this manner, each version **404** of the antenna response that is accepted at the interference and clutter cancellation module **124** can correspond to one feed port **402** of an antenna **122** or can correspond to feed ports **402** of multiple antennas **122**.

In general, any type of feed port **402** (including the feed ports **410-1**, **410-2**, **414-1**, **414-2**, **418-1**, or **418-2**) may be used to produce the multiple versions **404** if the feed ports **402** are distinct from one another (e.g., sense different phases, polarizations, angles of arrivals, or are otherwise associated with different antennas that are placed at different physical locations). By using multiple feed ports **402**, the described techniques for interference and/or clutter cancellation using cross-channel equalization **406** can operate without an extensive calibration process that characterizes a

15

mutual coupling channel, a modulated spur, or environmental clutter. As described in further detail with respect to FIG. 5, some of the components of the wireless transceiver 120 can be utilized for both proximity detection 130 and wireless communication 132.

FIG. 5 illustrates examples of a wireless transceiver 120, an interference and clutter cancellation module 124 (I&C cancellation module 124), and a modem 126. The wireless transceiver 120 can be implemented as a direct-conversion transceiver or a superheterodyne transceiver. In the depicted configuration, the wireless transceiver 120 includes a transmitter 502 and a receiver 504. The transmitter 502 is coupled between the modem 126 and the antenna array 216. The transmitter 502 is shown to include at least one signal generator 506, at least one digital-to-analog converter (DAC) 508, at least one mixer 510-1, and at least one amplifier 512-1 (e.g., a power amplifier). The signal generator 506 can generate a digital signal (e.g., a transmit signal 522), which may be used to derive the electromagnetic signal 226 or the uplink signal 202 (of FIGS. 2 and 3). The signal generator 506 or a portion thereof may be implemented in the modem 126. The transmitter 502 is connected to at least one feed port 402-1 or 402-2 of the antenna element 212-1, such as at least one of the differential feed ports 410 of the dipole antenna 408, at least one of the polarized feed ports 414 of the patch antenna 412, or at least one of the directional feed ports 418 of the bowtie antenna 416, as shown in FIG. 4.

The receiver 504 is coupled between the interference and clutter cancellation module 124 and the antenna array 216. In general, the receiver 504 includes at least two channels 514 (or layers), which are coupled to different feed ports 402 of one or more antenna elements 212. In the depicted configuration, channels 514-1 and 514-2 represent two parallel channels within the receiver 504 that are respectively connected to two feed ports 402-1 and 402-2 (of FIG. 4) of the antenna element 212-2. Although a single antenna element 212-2 is shown to be connected to the two channels 514-1 and 514-2, the channels 514-1 and 514-2 can alternatively be respectively connected to two different antenna elements 212, such as the second antenna element 212-2 and the Nth antenna element 212-N of FIG. 2. The channels 514-1 and 514-2 respectively include at least one amplifier 516-1 and 516-2 (e.g., a low-noise amplifier), at least one mixer 518-1 and 518-2, and analog-to-digital converters (ADC) 520-1 and 520-2. The digital-to-analog converter 508 and/or the analog-to-digital converters 520 may be implemented in the modem 126, or may be implemented in the wireless transceiver 120.

The wireless transceiver 120 also includes a local oscillator circuit 538, which generates a reference signal 524. The reference signal 524 enables the mixers 510-1, 518-1, and 518-2 to upconvert or downconvert analog signals within the transmitter 502 and the receiver 504. The reference signal 524 can have a continuous tone or can be modulated in frequency, as further described with respect to FIG. 6. During operation, the local oscillator circuit 538 provides an appropriate version of the reference signal 524 to support proximity detection 130 or wireless communication 132. The transmitter 502 and the receiver 504 can also include other additional components that are not depicted in FIG. 5 such as filters (e.g., low-pass filters or band-pass filters), phase shifters, additional mixers, switches, and so forth.

During wireless communication 132, the wireless transceiver 120 can transmit the uplink signal 202 or receive the downlink signal 204 (of FIGS. 2 and 3). In particular, the signal generator 506 generates the transmit signal 522,

16

which includes communication data. The digital-to-analog converter 508 converts the transmit signal 522 from the digital domain to the analog domain. The local oscillator circuit 538 generates the reference signal 524 having a steady (e.g., constant) frequency. The mixer 510-1 upconverts the transmit signal 522 to radio frequencies using the reference signal 524. The amplifier 512-1 amplifies the transmit signal 522, and the antenna element 212-1 transmits the transmit signal 522 as the uplink signal 202.

During wireless communication 132, the antenna element 212-2 can receive the downlink signal 204. At least one of the receive channels within the receiver 504 processes the downlink signal 204. For example, the amplifier 516-1 amplifies the downlink signal 204, and the mixer 518-1 downconverts the downlink signal 204 using the reference signal 524, which is the local oscillator signal. The analog-to-digital converter 520-1 converts the downlink signal 204 from the analog domain to the digital domain. The digital version of the downlink signal 204 can be passed to the modem 126 or a data processor in the modem for further processing. The interference and clutter cancellation module 124 can be bypassed during wireless communication 132.

During proximity detection 130, the transmitter 502 transmits the electromagnetic signal 226 via the antenna element 212-1. In particular, the signal generator 506 can generate the transmit signal 522, which can include a single continuous tone. The digital-to-analog converter 508 converts the transmit signal 522 from the digital domain to the analog domain. The local oscillator circuit 538 generates the reference signal 524, which is modulated in frequency. The mixer 510-1 upconverts and modulates the transmit signal 522 using the reference signal 524. The amplifier 512-1 amplifies the upconverted and modulated transmit signal 522, and the antenna element 212-1 transmits the amplified, upconverted, and modulated transmit signal 522 as the electromagnetic signal 226.

The receiver 504 receives different versions 404 of the antenna responses via the antenna element 212-2. The response of the antenna element 212-2 is separated into the versions 404-1 and 404-2 via the feed ports 402-1 and 402-2. Using the mixers 518-1 and 518-2, the channels 514-1 and 514-2 of the receiver 504 demodulate the versions 404-1 and 404-2 of the antenna response using the reference signal 524 and produce receive signals 526-1 and 526-2, respectively, which may be converted into digital version of the signals 526-1 and 526-2 using the ADCs 520-1 and 520-2.

The receive signals 526-1 and 526-2 can have one or more signal components or characteristics that are indicative of a presence of the object 206 and/or range to the object 206. The interference and clutter cancellation module 124 attenuates the interference signal 218 within one of the receive signals 526-1 and 526-2 to generate a filtered signal 528. In particular, the interference and clutter cancellation module 124 uses cross-channel equalization 406 to equalize the slow time-varying components of the interference signal 218 across the receive signals 526-1 and 526-2. After equalization, the interference and clutter cancellation module 124 uses one of the equalized receive signals to cancel the slow time-varying component and fast time-varying component within the other equalized receive signal. By attenuating the interference signal 218, the interference and clutter cancellation module 124 can prevent false detections and enable the signal component or characteristic associated with the object 206 to be detected. In this way, the filtered signal 528 substantially includes information representative of the object 206 (if present) and omits or filters the mutual-

17

coupling component 220, the modulated spur 222, and/or the clutter component 224 associated with the interference signal 218.

In FIG. 5, the modem 126 includes at least one proximity detection module 530 and at least one transmitter control module 532 (TX control module 532). The proximity detection module 530 obtains the filtered signal 528 and generates detection data 534, which indicates whether or not the object 206 is detected. The detection data 534 can include a range to the object 206.

Based on the detection data 534, the transmitter control module 532 generates at least one transmission parameter 536 that controls one or more transmission attributes for wireless communication 132. The transmission parameter 536 can specify one or more transmission-related aspects of the uplink signal 202, such as a power level, polarization, frequency, duration, beam shape, beam steering angle, a selected antenna that transmits the uplink signal 202 (e.g., another antenna that is on a different surface of the computing device 102 and is not obstructed by the object 206), or combinations thereof. Some transmission parameters 536 may be associated with beam management, such as those that define an unobstructed volume of space for beam sweeping. By specifying the transmission parameter 536, the modem 126 can, for example, cause the transmitter 502 to decrease power if an object 206 is close to the computing device 102 or increase power if the object 206 is at a farther range or is not detectable. The ability to detect the object 206 and control the transmitter 502 enables the modem 126 to balance the performance of the computing device 102 with regulatory compliance guidelines. In other implementations, the application processor 108 can perform one or more of these functions.

Although not explicitly shown, multiple antennas 122 (or multiple antenna elements 212) can be used to generate additional versions 404 of the antenna response (e.g., a third version or a fourth version) and provide additional receive signals 526 to the interference and clutter cancellation module 124 (e.g., a third receive signal 526 or a fourth receive signal 526). For example, two or more patch antennas 412 may be used to generate the antenna responses. With multiple filtered signals 528, the computing device 102 can increase a probability of detecting the object 206 (or accurately determining a range thereof) or decrease a probability of false alarms. The transmitter control module 532 can also make different adjustments based on which antennas 122 or what quantity of antennas 122 detect the object 206. In some cases, these adjustments may impact beam management by focusing available beams or targeting a spatial area for beam determination.

For example, in some situations, the object 206 may be closer to one of the antennas 122 than another, which enables the one antenna 122 to detect the object 206 while the other antenna 122 is unable to detect the object 206. In this case, the transmitter control module 532 can decrease a transmit power of the antenna 122 that detected the object 206 relative to the other antenna 122. In some implementations, the multiple antennas 122 can be used to further characterize the relationship between the object 206 and the antennas 122, such as by using triangulation or digital beamforming to estimate an angle to the object 206. In this way, the transmitter control module 532 can adjust the transmission parameter 536 to steer the uplink signal 202 away from the object 206. In general, the interference and clutter cancellation module 124 can provide interference and/or clutter cancellation between any two or more receive signals 526. Components of the local oscillator circuit 538

18

that enable the wireless transceiver 120 to selectively perform proximity detection 130 and wireless communication 132 are further described with respect to FIG. 6.

FIG. 6 illustrates an example local oscillator circuit 538 (LO circuit 538) for supporting proximity detection 130 and wireless communication 132. In the depicted configuration, the local oscillator circuit 538 includes a frequency-modulated local oscillator 602, a local oscillator 604, and a selection circuit 606. The frequency-modulated local oscillator 602 can be implemented using a voltage ramp generator 610 and a voltage-controlled oscillator 612. As an example, the voltage-controlled oscillator 612 can be implemented using a wideband open-loop voltage-controlled oscillator. By controlling an input voltage to the voltage-controlled oscillator 612, the voltage ramp generator 610 can provide a variety of different voltage ramps to enable the voltage-controlled oscillator 612 to generate a variety of different frequency-modulated local oscillator signals 614 (e.g., a linear-frequency modulated (LFM) signal, a sawtooth-frequency modulated signal, a triangular-frequency modulated signal, and so forth).

The local oscillator 604 can include, for example, a quartz crystal, an inductor-capacitor (LC) oscillator, an oscillator transistor (e.g., a metal-oxide semiconductor field-effective transistor (MOSFET)), a transmission line, a diode, a piezoelectric oscillator, and so forth. A configuration of the local oscillator 604 can enable a target phase noise and quality factor to be achieved for wireless communication 132. In general, the local oscillator 604 generates a local oscillator signal 616 (LO signal 616) with a steady (e.g., constant) frequency. Although not explicitly shown, the local oscillator circuit 538 can also include a phase lock loop or automatic gain control circuit. Either of these components can be coupled to the local oscillator 604 to enable the local oscillator 604 to oscillate at a (e.g., selectable) steady frequency.

The selection circuit 606 can include a switch or a multiplexer that is controlled by the modem 126 via a control signal 618. Based on the control signal 618, the selection circuit 606 connects or disconnects the frequency-modulated local oscillator 602 or the local oscillator 604 to or from the mixers 510-1, 518-1, and 518-2. If the control signal 618 is indicative of the wireless transceiver 120 performing proximity detection 130, the selection circuit 606 connects the frequency-modulated local oscillator 602 to the mixers 510-1, 518-1, and 518-2 to provide the frequency-modulated local oscillator signal 614 as the reference signal 524. Alternatively, if the control signal 618 is indicative of the wireless transceiver 120 performing wireless communication 132, the selection circuit 606 connects the local oscillator 604 to the mixers 510-1, 518-1, and 518-2 to provide the local oscillator signal 616 as the reference signal 524. The selection circuit 606 enables the wireless transceiver 120 to quickly transition between performing operations for proximity detection 130 or wireless communication 132.

Although the frequency-modulated local oscillator 602 and the selection circuit 606 are shown in FIG. 6, other implementations of the local oscillator circuit 538 may not include these components. In this case, the local oscillator 604 can provide the local oscillator signal 616 as the reference signal 524 for both proximity detection 130 and wireless communication 132. In this case, the signal generator 506 can apply a frequency modulation to the transmit signal 522 to enable proximity detection 130. In other examples, respective local oscillator circuitry for wireless communication 132 and proximity detection 130 are imple-

mented, and respective reference signals **524** are provided to the mixers **510-1**, **518-1**, and **518-2** shared for wireless communication **132** and proximity detection **130** or to respective mixers. Operations of the cross-channel equalizer **128** are further described with respect to FIGS. 7 and 8.

FIG. 7 illustrates an example plot **700-1** of an amplitude of the receive signal **526-1** or **526-2** across fast time and slow time. A duration of the receive signal **526-1** or **526-2** across the fast time corresponds to a duration of each pulse **702** within the receive signal **526-1** or **526-2**. A duration of the receive signal **526-1** or **526-2** across slow time represents an inter-pulse period (IPP) of the receive signal **526-1** or **526-2** (e.g., a duration between successive pulses of the electromagnetic signal **226**). For simplicity, the receive signal **526-1** or **526-2** is shown to include three pulses **702-1**, **702-2**, and **702-3** in FIG. 7. The receive signal **526-1** or **526-2**, however, can include any quantity of pulses **702**.

The amplitude (and phase) of each pulse **702** represents a summation of the receive signal **526-1** or **526-2** and the interference signal **218**. As described with respect to FIG. 3, the interference signal **218** can include the mutual-coupling component **220**, the modulated spur **222**, the clutter component **224**, or some combination thereof. These component signals are illustrated in plot **700-2** for one of the pulses **702-1** to **702-3**. As seen in the plot **700-2**, the mutual-coupling component **220** and the clutter component **224** represent slow time-varying components (or slow time-varying component signals). The amplitude and phase of the slow time-varying components do not change frequently over the duration of the pulse **702**. As such, the frequency of the slow time-varying components can be close to a baseband frequency. In contrast, an object-based signal component **704**, which represents the perturbation **210** associated with the near field or the radar receive signal associated with the far field, and the modulated spur **222** represent fast time-varying components (or fast time-varying component signals). The amplitude and/or phase of fast time-varying components can change frequently over the duration of a pulse **702**. The frequency of the fast time-varying components can be closer to the beat frequency compared to the baseband frequency.

In general, the object-based signal component **704** is uncorrelated between the two channels **514** due to random fluctuations in magnitude and/or phase caused by the object **206**. The object-based signal component **704** is also uncorrelated to the slow time-varying components. Components of the interference signal **218**, however, can be correlated between the two channels **514** within each pulse **702** of the receive signal **526-1** or **526-2**. The components of the interference signal **218** may be uncorrelated over successive pulses **702**. The mutual-coupling component **220** and the modulated spur **222** are co-linear because of their relationship to a same transmitter **502**. Also, the mutual-coupling component **220** and the modulated spur **222** are similar across the channels **514** within a scale factor, which may be a complex scale factor. To attenuate the interference signal **218**, the interference and clutter cancellation module **124** uses cross-channel equalization **406**, which is further described with respect to FIG. 8.

FIG. 8 illustrates an example implementation of the interference and clutter cancellation module **124**. In the depicted configuration, the interference and clutter cancellation module **124** includes the cross-channel equalizer **128**, an optional scaler **802**, and a summation circuit **804**. The cross-channel equalizer **128** is coupled to at least two channels **514** of the receiver **504**, the scaler **802**, and the

summation circuit **804**. During operation, the cross-channel equalizer **128** performs aspects of cross-channel equalization **406**.

The cross-channel equalizer **128** includes at least two slow-time extractors **806**, such as slow-time extractors **806-1** and **806-2** (ST extractors **806-1** and **806-2**). The cross-channel equalizer **128** also includes at least two multiplication circuits **808**, such as multiplication circuits **808-1** and **808-2**. The slow-time extractors **806-1** and **806-2** track and extract the slow time-varying components of the interference signal **218** (e.g., the mutual-coupling component **220** and/or the clutter component **224**). The slow-time extractors **806-1** and **806-2** can be implemented using, for example, an infinite-impulse-response (IIR) low-pass filter.

The scaler **802** determines and applies a scaling factor to enable one of the receive signals **526** to cancel slow time-varying components and correlated fast time-varying components within another one of the receive signals **526**. The scaling factor can have a magnitude component and/or a phase component. In an example implementation, the scaler **802** includes a least-squares module **810** and a delay module **812**.

During proximity detection **130**, the cross-channel equalizer **128** accepts at least two receive signals **526**, such as receive signals **526-1** and **526-2**. The slow-time extractor **806-1** extracts a first slow time-varying component **814-1** (STV component **814-1**) from the receive signal **526-1**. Similarly, the slow-time extractor **806-2** extracts a second slow time-varying component **814-2** (STV component **814-2**) from the receive signal **526-2**. The slow time-varying components **814-1** and **814-2** can each include the mutual-coupling component **220** and/or the clutter component **224**.

The cross-channel equalizer **128** equalizes (or makes similar) the slow time-varying components **814** within the receive signals **526**. In particular, the cross-channel equalizer **128** applies the slow time-varying component associated with one channel to the receive signal **526** associated with another channel. For example, the multiplication circuit **808-1** generates a first equalized receive signal **816-1** by multiplying the receive signal **526-1** with the second slow time-varying component **814-2**. Also, the multiplication circuit **808-2** generates a second equalized receive signal **816-2** by multiplying the receive signal **526-2** with the first slow time-varying component **814-1**.

The scaler **802** uses the least-squares module **810** and the equalized receive signals **816-1** and **816-2** to produce at least one weight **818** for scaling the equalized receive signal **816-2**. The scaler **802** generates a scaled equalized receive signal **820** by aligning and applying the weights **818** to the equalized receive signal **816-2** using the delay module **812**. Due to the cross-channel equalization **406** and the scaling, the scaled equalized receive signal **820** includes slow time-varying components and fast time-varying components with substantially similar amplitudes and phases as the slow time-varying components and the fast time-varying components within the equalized receive signal **816-1**.

The summation circuit **804** combines the equalized receive signal **816-1** and the scaled equalized receive signal **820** together in a way that attenuates the interference signal **218**. In the depicted configuration, the summation circuit **804** subtracts the scaled equalized receive signal **820** from the equalized receive signal **816-1** to generate the filtered signal **528**, but the equalized receive signal **816-1** may be scaled and subtracted from the equalized receive signal **816-2** in other implementations. In this way, the slow time-varying components and fast time-varying components associated with the interference signal **218** are attenuated

## 21

within the filtered signal **528** without meaningfully attenuating the object-based signal component **704**.

With cross-channel equalization **406**, the interference signal **218** is attenuated by a sufficient amount such that the computing device **102** does not detect or determine the mutual-coupling component **220**, the modulated spur **222**, and/or the clutter component **224** to be an object of interest. In some implementations, the magnitude of the mutual-coupling component **220**, the modulated spur **222**, and/or the clutter component **224** is less than a detection threshold and causes the computing device **102** to determine that these components are not associated with an object of interest. At the same time, the magnitude of the object-based signal component **704** is above the detection threshold and causes the computing device **102** to detect the one or more objects **206** that caused the object-based signal component **704**. This cancellation enables detection of weak signal components within the filtered signal **528** to be processed for proximity detection **130** and enables the computing device **102** to realize a target false-alarm rate performance.

The techniques for interference and clutter cancellation using cross-channel equalization **406** can be applied to more than two receive signals **526** (or more than two receive channels). For example, the interference and clutter cancellation module **124** can perform similar operations using a third and fourth receive signal **526**.

Although described with respect to proximity detection **130**, the techniques of implementing interference and/or clutter cancellation using cross-channel equalization can also be applied in other wireless applications, including those that utilize full-duplex operation in which transmission and reception occur during a same time interval.

FIG. **9** is a flow diagram illustrating an example process **900** for interference and/or clutter cancellation using cross-channel equalization. The process **900** is described in the form of a set of blocks **902-906** that specify operations that can be performed. However, operations are not necessarily limited to the order shown in FIG. **9** or described herein, for the operations may be implemented in alternative orders or in fully or partially overlapping manners. Operations represented by the illustrated blocks of the process **900** may be performed by a wireless transceiver **120** (e.g., of FIG. **1** or **5**). More specifically, the operations of the process **900** may be performed, in part, by an interference and clutter cancellation module **124** of FIGS. **1** and **8**.

At block **902**, an electromagnetic signal is transmitted using a first feed port of multiple feed ports. A modulated spur is generated based on the transmission of the electromagnetic signal. For example, the computing device **102** transmits the electromagnetic signal **226** using a first feed port **402** of multiple feed ports **402**, as shown in FIGS. **2-1** and **4**. The modulated spur **222** is generated based on the transmission of the electromagnetic signal **226**. The modulated spur **222** represents a fast time-varying component. The electromagnetic signal **226** produces the electromagnetic field **208** in a near field and the radar transmit signal in a far field.

At block **904**, two versions of a receive signal are respectively received via two feed ports of the multiple feed ports. The receive signal comprises a mutual-coupling component associated with the modulated spur and the transmission of the electromagnetic signal. For example, the computing device **102** receives two versions of the receive signal **404-1** and **404-2** using two feed ports **402-1** and **402-2** of the multiple feed ports **402**, as shown in FIGS. **4** and **5**. The receive signal comprises a component corresponding to a mutual-coupling component **220** associated with the modu-

## 22

lated spur **222** and the transmission of the electromagnetic signal **226**. The mutual-coupling component **220** represents a type of slow time-varying component. The receive signal can also include a clutter component **224**, which represents another type of slow time-varying component. If an object **206** is present, the receive signal can further include the object-based signal component **704**.

At block **906**, a filtered signal is generated by attenuating the mutual-coupling component and the modulated spur within one of the two versions of the receive signal using cross-channel equalization. For example, the interference and clutter cancellation module **124** generates the filtered signal **528** by attenuating the mutual-coupling component **220** and the modulated spur **222** within one of the two versions of the receive signal **404-1** or **404-2** using cross-channel equalization **406**, as described with respect to FIG. **8**. Cross-channel equalization **406** involves equalizing magnitudes of the slow time-varying components of the interference signal **218** across the receive signals **526-1** and **526-2** and using one of the equalized receive signals **816** to attenuate the slow time-varying component and/or the correlated fast time-varying component within the other equalized receive signal **816**.

Some aspects are described below.

Aspect 1: An apparatus comprising:

a wireless transceiver configured to:

be connected to multiple feed ports;

transmit an electromagnetic signal using a first feed port of the multiple feed ports, a modulated spur generated based on the transmission of the electromagnetic signal;

receive two versions of a receive signal respectively via two feed ports of the multiple feed ports, the receive signal comprising the modulated spur and a mutual-coupling component associated with the transmission of the electromagnetic signal; and

generate a filtered signal by attenuating the mutual-coupling component and the modulated spur within one of the two versions of the receive signal using cross-channel equalization.

Aspect 2: The apparatus of aspect 1, wherein:

the receive signal comprises a clutter component; and the wireless transceiver is configured to generate the filtered signal by attenuating the mutual-coupling component, the modulated spur, and the clutter component within the one of the two versions of the receive signal using the cross-channel equalization.

Aspect 3: The apparatus of aspect 1 or 2, wherein the wireless transceiver is configured to:

generate two equalized receive signals by equalizing the mutual-coupling component within the two versions of the receive signal; and

combine the two equalized receive signals to generate the filtered signal.

Aspect 4: The apparatus of aspect 3, wherein:

the two versions of the receive signal comprise a first receive signal and a second receive signal; and the wireless transceiver is configured to:

extract a first mutual-coupling component from the first receive signal;

extract a second mutual-coupling component from the second receive signal;

generate a first equalized receive signal by multiplying the first receive signal by the second mutual-coupling component; and

## 23

generate a second equalized receive signal by multiplying the second receive signal by the first mutual-coupling component.

Aspect 5: The apparatus of aspect 4, wherein the wireless transceiver is configured to:

generate a scaled equalized receive signal by applying a scale factor to the second equalized receive signal; and generate the filtered signal by subtracting the scaled equalized receive signal from the first equalized receive signal.

Aspect 6: The apparatus of any previous aspect, wherein the mutual coupling component has a magnitude or phase that varies across successive pulses of the electromagnetic signal but that remains relatively constant across an individual pulse of the electromagnetic signal.

Aspect 7: The apparatus of any previous aspect, wherein the modulated spur has a magnitude or phase that varies across one pulse of the electromagnetic signal.

Aspect 8: The apparatus of any previous aspect, wherein the two feed ports of the multiple feed ports are associated with a same antenna.

Aspect 9: The apparatus of any one of aspects 1 to 7, wherein the two feed ports of the multiple feed ports are associated with different polarizations.

Aspect 10: The apparatus of any previous aspect, wherein the two feed ports of the multiple feed ports are associated with different antennas.

Aspect 11: The apparatus of any previous aspect, wherein the wireless transceiver is configured to adjust a transmission parameter based on the filtered signal, the transmission parameter varying based on detection of an object.

Aspect 12: The apparatus of any previous aspect, wherein the wireless transceiver comprises a modem configured to generate the filtered signal.

Aspect 13: An apparatus comprising:

means for transmitting an electromagnetic signal using a first feed port of multiple feed ports, a modulated spur generated based on the transmission of the electromagnetic signal;

means for receiving two versions of a receive signal respectively via two feed ports of the multiple feed ports, the receive signal comprising the modulated spur and a mutual-coupling component associated with the transmission of the electromagnetic signal; and

means for generating a filtered signal by attenuating the mutual-coupling component and the modulated spur within one of the two versions of the receive signal using cross-channel equalization.

Aspect 14: The apparatus of aspect 13, wherein: the receive signal comprises a clutter component; and the means for generating the filtered signal is configured to attenuate the mutual-coupling component, the modulated spur, and the clutter component within the one of the two versions of the receive signal using the cross-channel equalization.

Aspect 15: The apparatus of aspect 13 or 14, wherein the means for generating the filtered signal comprises:

means for generating two equalized receive signals by equalizing the mutual-coupling component within the two versions of the receive signal; and

means for combining the two equalized receive signals to generate the filtered signal.

Aspect 16: The apparatus of aspect 15, wherein: the two versions of the receive signal comprise a first receive signal and a second receive signal; and

## 24

the means for generating the two equalized receive signals comprises:

means for extracting a first mutual-coupling component from the first receive signal;

means for extracting a second mutual-coupling component from the second receive signal;

means for generating a first equalized receive signal by multiplying the first receive signal by the second mutual-coupling component; and

means for generating a second equalized receive signal by multiplying the second receive signal by the first mutual-coupling component.

Aspect 17: The apparatus of aspect 16, wherein the means for generating the filtered signal comprises:

means for generating a scaled equalized receive signal by applying a scale factor to the second equalized receive signal; and

means for subtracting the scaled equalized receive signal from the first equalized receive signal.

Aspect 18: A method comprising:

transmitting an electromagnetic signal using a first feed port of multiple feed ports, a modulated spur generated based on the transmission of the electromagnetic signal;

receiving two versions of a receive signal respectively via two feed ports of the multiple feed ports, the receive signal comprising the modulated spur and a mutual-coupling component associated with the transmission of the electromagnetic signal; and

generating a filtered signal by attenuating the mutual-coupling component and the modulated spur within one of the two versions of the receive signal using cross-channel equalization.

Aspect 19: The method of aspect 18, wherein:

the receive signal comprises a clutter component; and the generating of the filtered signal comprises attenuating the mutual-coupling component, the modulated spur, and the clutter component within the one of the two versions of the receive signal using the cross-channel equalization.

Aspect 20: The method of aspect 18 or 19, wherein the generating of the filtered signal comprises:

generating two equalized receive signals by equalizing the mutual-coupling component within the two versions of the receive signal; and

combining the two equalized receive signals to generate the filtered signal.

Aspect 21: The method of aspect 20, wherein:

the two versions of the receive signal comprise a first receive signal and a second receive signal; and the generating of the two equalized receive signals comprises:

extracting a first mutual-coupling component from the first receive signal;

extracting a second mutual-coupling component from the second receive signal;

generating a first equalized receive signal by multiplying the first receive signal by the second mutual-coupling component; and

generating a second equalized receive signal by multiplying the second receive signal by the first mutual-coupling component.

Aspect 22: The method of aspect 21, further comprising: generating a scaled equalized receive signal by applying a scale factor to the second equalized receive signal,

25

wherein the generating of the filtered signal comprises generating the filtered signal by subtracting the scaled equalized receive signal from the first equalized receive signal.

Aspect 23: An apparatus comprising:

a wireless transceiver configured to:

be connected to multiple feed ports;

transmit an electromagnetic signal using a first feed port of the multiple feed ports, a modulated spur generated based on the transmission of the electromagnetic signal, the modulated spur comprising a fast time-varying component having a magnitude or phase that varies substantially within a duration of a pulse of the electromagnetic signal;

receive two versions of a receive signal respectively via two feed ports of the multiple feed ports, the receive signal comprising the modulated spur;

detect at least one object based on the receive signal; and

satisfy a target false-alarm rate in the presence of the modulated spur.

Aspect 24: The apparatus of aspect 23, wherein the wireless transceiver is configured to:

generate an electromagnetic field within a near field based on the transmission of the electromagnetic signal; and detect at least one object within the near field based on a perturbation in the electromagnetic field.

Aspect 25: The apparatus of claim 23, wherein the wireless transceiver is configured to:

generate a radar transmit signal within a far field based on the transmission of the electromagnetic signal; and detect at least one object within the far field based on a reflection version of the radar transmit signal.

Aspect 26: The apparatus of any one of aspects 23 to 25, wherein:

the magnitude or phase of the fast time-varying component has a median value within the duration of the pulse of the electromagnetic signal; and

the magnitude or phase of the fast time-varying component varies by at least 5% from the median value within the duration of the pulse of the electromagnetic signal.

Aspect 27: The apparatus of any one of aspects 23 to 26, wherein the wireless transceiver is configured to attenuate the fast time-varying component within one of the two versions of the receive signal by using cross-channel equalization.

Aspect 28: The apparatus of aspect 27, wherein a magnitude of the attenuated fast time-varying component is less than a detection threshold.

Aspect 29: The apparatus of aspect 27 or 28, wherein: the receive signal comprises a slow time-varying component having a magnitude or phase that varies across multiple pulses associated with the electromagnetic signal but does not substantially vary across an individual pulse associated with the electromagnetic signal; and

the wireless transceiver is configured to attenuate the slow time-varying component within the one of the two versions of the receive signal based, at least in part, on using the cross-channel equalization.

Aspect 30: The apparatus of aspect 29, wherein the slow time-varying component comprises a mutual-coupling component or a clutter component.

Unless context dictates otherwise, use herein of the word “or” may be considered use of an “inclusive or,” or a term that permits inclusion or application of one or more items that are linked by the word “or” (e.g., a phrase “A or B” may

26

be interpreted as permitting just “A,” as permitting just “B,” or as permitting both “A” and “B”). As used herein, a phrase referring to “at least one of” a list of items refers to any combination of those items, including single members. As an example, “at least one of: a, b, or c” is intended to cover: a, b, c, a-b, a-c, b-c, and a-b-c, as well as any combination with multiples of the same element (e.g., a-a, a-a-a, a-a-b, a-a-c, a-b-b, a-c-c, b-b, b-b-b, b-b-c, c-c, and c-c-c or any other ordering of a, b, and c). Further, items represented in the accompanying figures and terms discussed herein may be indicative of one or more items or terms, and thus reference may be made interchangeably to single or plural forms of the items and terms in this written description. Finally, although subject matter has been described in language specific to structural features or methodological operations, it is to be understood that the subject matter defined in the appended claims is not necessarily limited to the specific features or operations described above, including not necessarily being limited to the organizations in which features are arranged or the orders in which operations are performed.

What is claimed is:

1. An apparatus comprising:

a wireless transceiver configured to:

be connected to multiple feed ports;

transmit an electromagnetic signal using a first feed port of the multiple feed ports, a modulated spur generated based on the transmission of the electromagnetic signal;

receive two versions of a receive signal respectively via two feed ports of the multiple feed ports, the receive signal comprising the modulated spur and a mutual-coupling component associated with the transmission of the electromagnetic signal; and

generate a filtered signal by attenuating the mutual-coupling component and the modulated spur within one of the two versions of the receive signal using cross-channel equalization.

2. The apparatus of claim 1, wherein:

the receive signal comprises a clutter component; and the wireless transceiver is configured to generate the filtered signal by attenuating the mutual-coupling component, the modulated spur, and the clutter component within the one of the two versions of the receive signal using the cross-channel equalization.

3. The apparatus of claim 1, wherein the wireless transceiver is configured to:

generate two equalized receive signals by equalizing the mutual-coupling component within the two versions of the receive signal; and

combine the two equalized receive signals to generate the filtered signal.

4. The apparatus of claim 3, wherein:

the two versions of the receive signal comprise a first receive signal and a second receive signal; and

the wireless transceiver is configured to: extract a first mutual-coupling component from the first receive signal;

extract a second mutual-coupling component from the second receive signal;

generate a first equalized receive signal by multiplying the first receive signal by the second mutual-coupling component; and

generate a second equalized receive signal by multiplying the second receive signal by the first mutual-coupling component.

27

5. The apparatus of claim 4, wherein the wireless transceiver is configured to:

generate a scaled equalized receive signal by applying a scale factor to the second equalized receive signal; and generate the filtered signal by subtracting the scaled equalized receive signal from the first equalized receive signal.

6. The apparatus of claim 1, wherein the mutual-coupling component has a magnitude or phase that varies across successive pulses of the electromagnetic signal but that remains relatively constant across an individual pulse of the electromagnetic signal.

7. The apparatus of claim 1, wherein the modulated spur has a magnitude or phase that varies across one pulse of the electromagnetic signal.

8. The apparatus of claim 1, wherein the two feed ports of the multiple feed ports are associated with a same antenna.

9. The apparatus of claim 1, wherein the two feed ports of the multiple feed ports are associated with different polarizations.

10. The apparatus of claim 1, wherein the two feed ports of the multiple feed ports are associated with different antennas.

11. The apparatus of claim 1, wherein the wireless transceiver is configured to adjust a transmission parameter based on the filtered signal, the transmission parameter varying based on detection of an object.

12. The apparatus of claim 1, wherein the wireless transceiver comprises a modem configured to generate the filtered signal.

13. An apparatus comprising:

means for transmitting an electromagnetic signal using a first feed port of multiple feed ports, a modulated spur generated based on the transmission of the electromagnetic signal;

means for receiving two versions of a receive signal respectively via two feed ports of the multiple feed ports, the receive signal comprising the modulated spur and a mutual-coupling component associated with the transmission of the electromagnetic signal; and

means for generating a filtered signal by attenuating the mutual-coupling component and the modulated spur within one of the two versions of the receive signal using cross-channel equalization.

14. The apparatus of claim 13, wherein: the receive signal comprises a clutter component; and the means for generating the filtered signal is configured to attenuate the mutual-coupling component, the modulated spur, and the clutter component within the one of the two versions of the receive signal using the cross-channel equalization.

15. The apparatus of claim 13, wherein the means for generating the filtered signal comprises:

means for generating two equalized receive signals by equalizing the mutual-coupling component within the two versions of the receive signal; and

means for combining the two equalized receive signals to generate the filtered signal.

16. The apparatus of claim 15, wherein:

the two versions of the receive signal comprise a first receive signal and a second receive signal; and the means for generating the two equalized receive signals comprises:

means for extracting a first mutual-coupling component from the first receive signal;

means for extracting a second mutual-coupling component from the second receive signal;

28

means for generating a first equalized receive signal by multiplying the first receive signal by the second mutual-coupling component; and

means for generating a second equalized receive signal by multiplying the second receive signal by the first mutual-coupling component.

17. The apparatus of claim 16, wherein the means for generating the filtered signal comprises:

means for generating a scaled equalized receive signal by applying a scale factor to the second equalized receive signal; and

means for subtracting the scaled equalized receive signal from the first equalized receive signal.

18. A method comprising:

transmitting an electromagnetic signal using a first feed port of multiple feed ports, a modulated spur generated based on the transmission of the electromagnetic signal;

receiving two versions of a receive signal respectively via two feed ports of the multiple feed ports, the receive signal comprising the modulated spur and a mutual-coupling component associated with the transmission of the electromagnetic signal; and

generating a filtered signal by attenuating the mutual-coupling component and the modulated spur within one of the two versions of the receive signal using cross-channel equalization.

19. The method of claim 18, wherein:

the receive signal comprises a clutter component; and the generating of the filtered signal comprises attenuating the mutual-coupling component, the modulated spur, and the clutter component within the one of the two versions of the receive signal using the cross-channel equalization.

20. The method of claim 18, wherein the generating of the filtered signal comprises:

generating two equalized receive signals by equalizing the mutual-coupling component within the two versions of the receive signal; and

combining the two equalized receive signals to generate the filtered signal.

21. The method of claim 20, wherein:

the two versions of the receive signal comprise a first receive signal and a second receive signal; and

the generating of the two equalized receive signals comprises:

extracting a first mutual-coupling component from the first receive signal;

extracting a second mutual-coupling component from the second receive signal;

generating a first equalized receive signal by multiplying the first receive signal by the second mutual-coupling component; and

generating a second equalized receive signal by multiplying the second receive signal by the first mutual-coupling component.

22. The method of claim 21, further comprising:

generating a scaled equalized receive signal by applying a scale factor to the second equalized receive signal,

wherein the generating of the filtered signal comprises generating the filtered signal by subtracting the scaled equalized receive signal from the first equalized receive signal.

29

23. An apparatus comprising:  
 a wireless transceiver configured to:  
   be connected to multiple feed ports;  
   transmit an electromagnetic signal using a first feed  
   port of the multiple feed ports, a modulated spur  
   generated based on the transmission of the electro-  
   magnetic signal, the modulated spur comprising a  
   fast time-varying component having a magnitude or  
   phase that varies substantially within a duration of a  
   pulse of the electromagnetic signal;  
   receive two versions of a receive signal respectively via  
   two feed ports of the multiple feed ports, the receive  
   signal comprising the modulated spur; and  
   satisfy a target false-alarm rate in the presence of the  
   modulated spur.
24. The apparatus of claim 23, wherein the wireless  
 transceiver is configured to:  
   generate an electromagnetic field within a near field based  
   on the transmission of the electromagnetic signal; and  
   detect at least one object within the near field based on a  
   perturbation in the electromagnetic field.
25. The apparatus of claim 23, wherein the wireless  
 transceiver is configured to:  
   generate a radar transmit signal within a far field based on  
   the transmission of the electromagnetic signal; and  
   detect at least one object within the far field based on a  
   reflection version of the radar transmit signal.

30

26. The apparatus of claim 23, wherein:  
   the magnitude or phase of the fast time-varying compo-  
   nent has a median value within the duration of the pulse  
   of the electromagnetic signal; and  
   the magnitude or phase of the fast time-varying compo-  
   nent varies by at least 5% from the median value within  
   the duration of the pulse of the electromagnetic signal.
27. The apparatus of claim 23, wherein the wireless  
 transceiver is configured to attenuate the fast time-varying  
 component within one of the two versions of the receive  
 signal by using cross-channel equalization.
28. The apparatus of claim 27, wherein a magnitude of the  
 attenuated fast time-varying component is less than a detec-  
 tion threshold.
29. The apparatus of claim 27, wherein: the receive signal  
 comprises a slow time-varying component having a magni-  
 tude or phase that varies across multiple pulses associated  
 with the electromagnetic signal but does not substantially  
 vary across an individual pulse associated with the electro-  
 magnetic signal; and  
   the wireless transceiver is configured to attenuate the slow  
   time-varying component within the one of the two  
   versions of the receive signal based, at least in part, on  
   using the cross-channel equalization.
30. The apparatus of claim 29, wherein the slow time-  
 varying component comprises a mutual-coupling compo-  
 nent or a clutter component.
