(57) **ABSTRACT**
Methods and apparatuses for dynamic power reduction in ultrasound systems are described. Subsystems including a first subsystem to be placed in a reduced power consumption state are determined. The first subsystem includes a receive path having a receiver to receive acoustic signals representing echoes. A control subsystem to control clocking of the receive path in response to at least one of a plurality of real-time signals is determined. The control subsystem is configured to provide one or more clocks to the receive path to turn on the receiver while valid echo signals are expected to arrive at the receiver. At least one of the plurality of real-time signals indicates a state of imaging operations. The control subsystem is configured to provide one or more clocks to the receive path during a first mode based on the state of the imaging operations.

DYNAMIC POWER REDUCTION TECHNIQUE FOR ULTRASOUND SYSTEMS

CROSS-REFERENCE TO RELATED APPLICATIONS

[0001] The present application is a continuation of and claims the benefit of U.S. patent application Ser. No. 18/731,840, filed Jun. 3, 2024 and entitled “Dynamic Power Reduction Technique for Ultrasound Systems”, which is a continuation of U.S. patent application Ser. No. 18/132,125, filed Apr. 7, 2023, and entitled “Dynamic Power Reduction Technique for Ultrasound Systems” that has issued as U.S. Pat. No. 12,038,800 on Jul. 16, 2024, which is a continuation of and claims the benefit of U.S. patent application Ser. No. 17/725,174, filed Apr. 20, 2022, and entitled “Dynamic Power Reduction Technique for Ultrasound Systems,” that has issued as U.S. Pat. No. 11,650,651 on May 16, 2023, which is a continuation of and claims the benefit of U.S. patent application Ser. No. 16/803,726, filed on Feb. 27, 2020, and entitled “Dynamic Power Reduction Technique for Ultrasound Systems,” that has issued as U.S. Pat. No. 11,493,979 on Nov. 8, 2022, and are incorporated herein by reference in their entirety.

FIELD OF THE INVENTION

[0002] Embodiments of the present invention relate generally to ultrasound systems; more particularly, embodiments of the present invention relate to performing power management in ultrasound systems based on real-time signals.

BACKGROUND

[0003] System power consumption in an ultrasound machine represents a significant problem for a designer. There are a number of adverse effects resulting from high system power consumption. Such ultrasound machines include larger, more expensive power supplies, have shorter battery lives, increased internal operating temperature, utilize active cooling components that add system cost, complexity and noise, and have an increased physical footprint.

[0004] Power consumption has been addressed at a macro level. More specifically, from a historical perspective, the power consumption problem in ultrasound machines has been addressed by defining sleep states for the machine that are generally under the control of the ultrasound machine's software. In the sleep state(s), portions of the system are put in a low power state (e.g., a lower power consumption state) by slowing or stopping the digital clock(s) controlling the block(s). The result is placing portions of the system in a lower power state is the reduction, and potentially minimization, of the dynamic power of the system. These states are generally defined at a macro level such that they do not occur when performing macro functions such as active imaging, and generally are applied when the ultrasound machine is idle.

[0005] FIG. 1 illustrates power usage at a macro level during an ultrasound exam. In the Imaging state, data is acquired and displayed in real-time. At this time, the system power consumption is generally at a maximum as most of the electronics are active. When the user stops imaging and reviews the acquired data, the system software can shut down most of the electronics associated with data acquisition while leaving the display and image recall electronics

running. This state of the ultrasound machine is often referred to as a Freeze state. During an exam, the user may toggle between Imaging and Freeze states multiple times. Finally, after a certain time duration in the Freeze state, the system software may shut down the display and enter an even lower power state depicted as Idle in FIG. 1.

[0006] To exploit the sleep state concept, the system software must be written to recognize opportunities to go to sleep and events requiring the system to wake up. The net effect is that the software design and verification are complicated to achieve power savings.

SUMMARY OF THE INVENTION

[0007] A dynamic power reduction method and apparatus for use in an ultrasound system are described. In one embodiment, the ultrasound system comprises: a transducer assembly and imaging subsystem having a transmit data path having a transmitter to transmit acoustic signals and a receive data path having including signal acquisition circuitry with a receiver to receive acoustic signals representing echoes; a plurality of real-time signals indicative of status of imaging operations being performed by the transmit and receive paths; a clock generator to generate one or more clocks for use by the transmit and receive data paths; clock gating circuitry coupled to the clock generator and the transmit and receive paths and having circuits to gate clocks to at least one of the transmit and receive paths; and a clock gating controller coupled to the clock gating circuitry to control the circuits to gate or pass clock signals to at least one of the transmit and receive paths automatically in response to receipt of one or more signals from the plurality of real-time signals.

BRIEF DESCRIPTION OF THE DRAWINGS

[0008] The present invention will be understood more fully from the detailed description given below and from the accompanying drawings of various embodiments of the invention, which, however, should not be taken to limit the invention to the specific embodiments, but are for explanation and understanding only.

[0009] FIG. 1 illustrates power usage at a macro level during an ultrasound exam.

[0010] FIG. 2 illustrates one embodiment of an ultrasound transducer probe having an ultrasound transducer assembly.

[0011] FIG. 3 illustrates a simplified description of frame acquisition for display performed by an ultrasound machine.

[0012] FIG. 4 illustrates the activity of one embodiment of an ultrasound machine while imaging.

[0013] FIG. 5 illustrates basic actions of the clock(s) of a receive path of an ultrasound machine.

[0014] FIG. 6 is a block diagram of one embodiment of a portion of an ultrasound machine.

[0015] FIG. 7 is a flow diagram of one embodiment of a process for setting up dynamic power reduction for an ultrasound machine.

[0016] FIG. 8 is a flow diagram of one embodiment of a power reduction process for use by an ultrasound machine.

DETAILED DESCRIPTION

[0017] In the following description, numerous details are set forth to provide a more thorough explanation of the present invention. It will be apparent, however, to one skilled in the art, that the present invention may be practiced

without these specific details. In other instances, well-known structures and devices are shown in block diagram form, rather than in detail, in order to avoid obscuring the present invention.

[0018] An ultrasound system having dynamic power reduction and method for using the same are disclosed. In one embodiment, the dynamic power reduction is performed using hardware of an acoustic signal path to automatically detect power saving and transparently control digital clocks without the intervention of the system software. In one embodiment, the hardware-based dynamic power reduction is performed in cooperation with or in addition to the macro sleep conditions discussed above. In one embodiment, the hardware-based dynamic power reduction is configured to reduce power while actively imaging. In one embodiment, the power reduction is equal to or greater than the software-controlled sleep techniques discussed above and have the added benefit of no additional software complexity.

[0019] FIG. 2 illustrates one embodiment of an ultrasound transducer probe having an ultrasound transducer assembly configured in accordance with an embodiment of the disclosed technology. Referring to FIG. 2, ultrasound transducer probe **200** includes an enclosure **210** extending between a distal end portion **212** and a proximal end portion **214**. Enclosure **210** is configured to carry or house system electronics (e.g., one or more processors, integrated circuits, ASICs, FPGAs, beamformers, batteries and/or other power sources) disposed in an interior portion or cavity of enclosure **210**. The system electronics (not shown) are electrically coupled to an ultrasound imaging system **230** via a cable **218** that is attached to the proximal end of the probe.

[0020] At the probe tip, a transducer assembly **220** having one or more transducer elements is electrically coupled to the system electronics. In operation, transducer assembly **220** transmits ultrasound energy from the one or more transducer elements toward a subject and receives ultrasound echoes from the subject. The ultrasound echoes are converted into electrical signals by transmit receive circuitry and electrically transmitted to the system electronics and to electronics (e.g., one or more processors, memory modules, beamformers, FPGAs, etc.) in ultrasound imaging system **230** configured to process the electrical signals and form one or more ultrasound images.

[0021] Capturing ultrasound data from a subject using an exemplary transducer assembly (e.g., the transducer assembly **220**) generally includes generating ultrasound, transmitting ultrasound into the subject, and receiving ultrasound reflected by the subject. A wide range of frequencies of ultrasound may be used to capture ultrasound data, such as, for example, low frequency ultrasound (e.g., less than 15 MHz) and/or high frequency ultrasound (e.g., greater than or equal to 15 MHz) can be used. Those of ordinary skill in the art can readily determine which frequency range to use based on factors such as, for example, but not limited to, depth of imaging and/or desired resolution.

[0022] In one embodiment, ultrasound imaging system **230** includes ultrasound control subsystem **231** having one or more processors. At least one processor causes electrical currents to be sent to the transducer(s) of probe **200** to emit sound waves and also receives the electrical pulses from the probe that were created from the returning echoes. A processor processes the raw data associated with the received electrical pulses and forms an image that is sent to ultrasound imaging subsystem **232**, which displays the image on

display screen **233**. Thus, display screen **233** displays ultrasound images from the ultrasound data processed by the processor of ultrasound control subsystem **231**.

[0023] In one embodiment, the ultrasound system also has one or more user input devices (e.g., a keyboard, a cursor control device, etc.) that inputs data and allows the taking of measurements from the display of the ultrasound display subsystem, a disk storage device (e.g., hard, floppy, compact disks (CD), digital video discs (DVDs)) for storing the acquired images, and a printer that prints the image from the displayed data. These also have not been shown in FIG. 2 to avoid obscuring the techniques disclosed herein.

[0024] FIG. 3 illustrates a simplified description of frame acquisition for display performed by an ultrasound machine. A frame represents the amount of data needed to form an image on a display. The successive acquisition and display of frames of data allows the ultrasound machine to show the motion of the object being observed.

[0025] Referring to FIG. 3, a frame consists of multiple (N) transmit beams **303** generated by transducer **301** toward an object of interest **304** that is located at a depth from skin line **302** and the echo returns from each of the transmit beams **303**. In one embodiment, these beams **303** are closely spaced in time to minimize the time to produce a frame. The frame rate, which indicates how often the display is updated, is generally related to the acquisition time of the frame. For many applications, the ultrasound machine does not need to operate at a maximum frame rate either because the display electronics cannot keep up or because the user cannot perceive changes from one frame to the next. There is often a gap from the end of one frame to the start of the next which is referred to herein as the Frame Holdoff Time. FIG. 4 illustrates the activity of one embodiment of an ultrasound machine while imaging. Referring to FIG. 4, multiple transmit/receive beams are shown for Frames **1-N** that are obtained over time. Between each of these frames is the Frame Holdoff Time.

[0026] Each of the N transmit/receive beams **303** in a frame can be further examined in terms of its activity. For the sake of simplicity, the receive path is discussed below in terms of dynamic power reduction; however, it should be understood that the dynamic power reduction techniques disclosed herein may be applied to the transmit path as well. In one embodiment, the transmit path refers to the electronics used to excite the individual transducer elements. Some common components of the transmit path are: a group of high voltage driver circuits used to energize the transducer elements, a set of delay circuits controlling the timing of signals to the high voltage drivers to control the focus of the generated acoustic beam and a waveform table (e.g., lookup table (LUT) or other memory) controlling the shape of the signal into the high voltage drivers. In one embodiment, the receive path comprises the electronics used to process the low level echoes detected by the transducer elements in response to the transmit beam. Typical operations performed by the electronics are: amplification of the return signals using both fixed and time variable amplifiers, filtering, signal conversion from the analog to the digital domain and receive beamforming. This last operation includes time variable digital gains to create a receive aperture with time alignment of the digitally sampled return signals to form a coherent receive beam.

[0027] FIG. 5 illustrates basic actions of a receive path's clock(s) of one embodiment of an ultrasound machine.

There are a number of events used to selectively turn the receive path clock on/off dynamically within the context of the timing for a single transmit/receive beam. This is a departure from the macro control described above as the clock is dynamically starting and stopping during imaging. In one embodiment, the decision to start and stop the clock is based on real-time signals during data acquisition.

[0028] Referring to FIG. 5, the receive path clock is off (501). The receive signal path has many parameters that are unique for each receive channel during a given transmit/receive operation. In one embodiment, the parameters are those discussed above with respect to the transmit and receive paths. In one embodiment, the parameters include individual transmit and receive delays for each transmitter and receiver, data to control time variable gains, and/or channel calibration data. In one embodiment, the clock to the receive path is active (502) in order to program the parameters (T1->T2 in FIG. 5). When programming has completed, the clock can be shut off (503) and remain off (T2->T3) until valid echo return data reaches the transducer at which point the clock remains on (504) for the duration of the data acquisition time (T3->T4). Finally, the clock shuts off (505) and remains off until it is time to re-program the receive path for the next acquisition.

[0029] FIG. 6 is a block diagram of one embodiment of a portion of an ultrasound machine. Referring to FIG. 6, the ultrasound machine includes a clock gating control subsystem 601 coupled to a clock generator 602. In one embodiment, clock generator 602 includes a phased lock loop (PLL) 603 to generate clock signals. Clock generator 602 provides free running clocks 606 to subsystem 607 and ultrasound control subsystem 610. In one embodiment, subsystem 607 is part of the imaging subsystem and includes receive path 608 to receive and process acoustic signals (e.g., echoes) and a status and control module to provide state and control signals to clock gating control subsystem 601. In one embodiment, subsystem 607 includes the transmit path for the ultrasound machine to generate and transmit acoustic signals for the ultrasound machine.

[0030] Ultrasound control subsystem 610 controls operations of the ultrasound machine. In one embodiment, ultrasound control subsystem 610 generates status signals. In one embodiment, ultrasound control subsystem 610 generates status signals that are sent to and received by clock gating control subsystem 601.

[0031] In one embodiment, the signals that are generated by subsystem 607 and ultrasound control subsystem 610 that are sent to and received by clock gating control subsystem 601 are real-time signals that comprise: a first signal indicating a user has indicated a desire to freeze the image currently being display on a display of the ultrasound system (e.g., freeze signal 621); a second signal indicating a start of a line (e.g., Start of Line signal 622); a third signal indicating registers are being programmed (the registers being for the receive path) (e.g., programming registers signal 623); a fourth signal indicating the receive path has been enabled to receive echoed acoustic signals (e.g., Receive_start signal 624); and a fifth signal indicating an end of the line has been reached (e.g., End of Line signal 625).

[0032] Clock gating control subsystem 601 uses signals 621-625 to perform clock control by gating/ungating clocks to different portions of the ultrasound machine. In one embodiment, clock gating control subsystem 601 uses signals 621-625 to perform clock control by gating/ungating

clocks to different portions of the ultrasound machine according to the typical transmit/receive beam timeline during acquisition as shown in FIG. 5. For example, clock gating control subsystem 601 controls gate 604 to enable and disable one or more clocks 605 to receive path 608. For example, in response to freeze signal 621, clock gating control subsystem 601 controls gate 604 to disable one or more clocks 605 to receive path 608 as no echoes are going to be received while a user of the ultrasound machine freezes the display.

[0033] As another example, in response to programming registers signal 623, clock gating control subsystem 601 controls gate 604 to enable one or more clocks 605 to receive path 608 while registers are being programmed. After programming has been completed as indicated by a change in the programming registers signal 623, clock gating control subsystem 601 can control gate 604 to disable one or more clocks 605 to receive path 608 to place it in a reduced power consumption state until after the transmit section has finished transmitting beams and there are valid echoes returning to the transducer to be received by receive path 608.

[0034] As yet another example, in response to receive_start signal 624, clock gating control subsystem 601 controls gate 604 to enable one or more clocks 605 to receive path 608 to enable receive path 608 to be powered to receive valid echoes return to the transducer to be received and otherwise disable clocks 605 to receive path to place it in a reduced power consumption state. Similarly, clock gating control subsystem 601 uses receive_start signal 624 to disable one or more clocks 605 to the transmit path to place the transmit path in a reduced power consumption state while receive path 608 is receiving echoes (as the transmit path will not be transmitting beams during that time).

[0035] After finishing the receipt of echoes and an end of line has been reached as indicated by End of Line signal 625, clock gating control subsystem 601 can control gate 604 to disable one or more clocks 605 to receive path 608 to place it in a reduced power consumption state until a new line is going to be started and/or programming of registers is to occur.

[0036] As yet another example, in response to start of line signal 622, clock gating control subsystem 601 controls gate 604 to enable one or more clocks to the transmit path to enable the transmit path to be powered to transmit beams from the transducer. In one embodiment, a similar clock gating approach is applied to the transmit path in an effort to reduce power (i.e., to shut down the transmit logic when not transmitting).

[0037] In one embodiment, clock gating control subsystem 601 uses signals 621-625 along with one or more conditions (e.g., conditions 640) to perform clock control by gating/ungating clocks to different portions of the ultrasound machine. In this case, the clock control that is performed for certain sequences differs from that of the transmit/receive beam timeline during image acquisition shown in FIG. 5. Thus, clock gating control subsystem 601 handles other control sequences when performing clock control by gating/ungating clocks to different portions of the ultrasound machine.

[0038] In one embodiment, these sequences include one or more of the following:

[0039] 1) imaging modes where register reprogramming is not needed between successive transmit/re-

ceive beams, and thus the time interval T1->T2 is 0. This is the case, for example, when reshooting of a line into an object to obtain a series of data for use in measuring changes in motion in the object on the line; if reshooting the line, the clock(s) does not need to be turned on during the time when the registers are normally being programmed; thus, the clock stays off until it is time to capture the returning echo values.

[0040] 2) dummy ping generation where no data is acquired by receive path 608 but a time delay between transmit/receive beams is desired. In this case, there is no need to program registers during a “dummy” ping generation because transmit and receive are not going to occur. Thus, the clock(s) that are normally turned on when programming the registers can remain off; and

[0041] 3) system initialization or a mode change where no data is acquired by receive path but register programming is necessary.

[0042] In the case of imaging modes where register reprogramming is not needed between successive transmit/receive beams, clock gating control subsystem 601 maintains the receive path in a reduced power state from T0 to T3 of FIG. 5. This behavior is identified by one of the input conditions 640. The condition represents a deviation from the baseline behavior in which the clock is enabled in response to 623.

[0043] In one embodiment, in the case of dummy ping generation, clock gating control subsystem 601 controls, using clock gating controller subsystem 601, the clocks to the receive path in response to a one of conditions 640 indicating whether or not the transducer is in ping generation mode. In such a case, since no data is to be acquired but a time delay between the transmit/receive beams is desired, if the ultrasound machine is in a ping generation mode, clock gating controller subsystem 601 maintains the clock signals to the receive path in a reduced power mode via clock gating when the receive_start signal 624 indicates that receive path 608 is to receive echoes.

[0044] In one embodiment, in the case of system initialization or a mode change mode changes refers to imaging modes and when the type of data being displayed changes. An example of this might be to switch from a gray scale image to a color image in this case the imaging stops and the system is re-initialized to acquire color data, clock gating control subsystem 601 controls, using clock gating controller subsystem 601, the clocks to the receive path in response to a one of conditions 640 indicating whether the ultrasound machine is in system initialization or a mode change. In such a case, clock gating control subsystem 601 enables clocks to the receive path when programming the registers but then does not re-enable the clocks to the receive path according to the time that echoes are to be returned to the transducer according to the time line in FIG. 5 as no data acquisition is to take place.

[0045] FIG. 7 is a flow diagram of one embodiment of a process to set up a dynamic power reduction process. The process is performed by processing logic that comprises hardware (circuitry, dedicated logic, etc.), software (e.g., software running on a chip), firmware, or a combination of the three.

[0046] Referring to FIG. 7, the process begins by defining subsystems that may be placed in low power states and the time and events associated with shutting off their clocks (processing block 701) and all system clocks (processing

block 702). In one embodiment, dynamically gated clocks are treated as independent clocks derived from free running clocks at the same frequency. More specifically, in one embodiment, for each clock, processing logic examines all blocks attached to it and identifies which of these blocks contains logic that can be turned off at some point during normal operation without changing the block's function. Then the events associated with stopping the clock are listed.

[0047] The process continues by grouping, for each subsystem, the registers into clock domains based on their activity in the system (processing block 703). After grouping, the process identifies registers that will remain active at all times as they interact with the system software and may be accessed at any time (processing block 704), identifies registers that can enter a sleep mode only when the system is not imaging. These registers may control other system components with long wakeup times (processing block 705), and identifies registers that can be shut off at various times while actively imaging (processing block 706). In one embodiment, these are registers in subsystem's data path or data path control.

[0048] Lastly, the process defines, for each subsystem, a clock control a structure based on the inputs defined in processing block 701. In one embodiment, the control structure is clocked by a free running clock and generates the real-time controls for its corresponding clock gating circuit.

[0049] FIG. 8 is a flow diagram of one embodiment of a power reduction process for use by an ultrasound machine. The process is performed by processing logic that comprises hardware (circuitry, dedicated logic, etc.), software (e.g., software running on a chip), firmware, or a combination of the three.

[0050] Referring to FIG. 8, the process begins with processing logic monitoring a plurality of real-time signals indicative of status of imaging operations being performed by the transmit and receive paths of an ultrasound transducer during use of the ultrasound transducer (processing block 801).

[0051] While monitoring the real-time signals, processing logic automatically detects a state in which one or both of the transmit and receive paths of an ultrasound transducer can be placed in a reduce power consumption state in response to receipt of one or more signals from the plurality of real-time signals (processing block 802).

[0052] In response to detecting the state, processing logic places one or both of the transmit and receive paths of an ultrasound transducer in a reduce power consumption state using clock gating circuitry controlled by the one or more real-time signals (processing block 803).

[0053] In one embodiment, placing one or both of the transmit and receive paths of an ultrasound transducer in a reduce power consumption state comprises controlling, using a clock gating controller, the clock gating circuitry, in response to the one or more of the plurality of real-time signals, to gate a clock to the transmit path to turn off a transmitter of the transmit path after transmitting an acoustic signal for a line and controlling the clock gating circuitry to pass a previously gated second clock signal to the receive path to turn on a receiver when valid echo signals are expected to arrive at the receiver.

[0054] In one embodiment, placing one or both of the transmit and receive paths of an ultrasound transducer in a reduce power consumption state comprises controlling, using a clock gating controller, the clock gating circuitry, in

response to the one or more of the real-time signals, to gate clocks to the transmit and receive paths at an end of one frame until another frame is started.

[0055] In one embodiment, placing one or both of the transmit and receive paths of an ultrasound transducer in a reduce power consumption state comprises controlling, using a clock gating controller, the clock gating circuitry, responsive to a first condition to ignore a first signal of the plurality of real-time signals indicating one or more receive path registers are being programmed, when the imaging mode indicates that reprogramming of the one or more receive path registers for transmit and receive operations for successive beams is not needed. In one embodiment, placing one or both of the transmit and receive paths of an ultrasound transducer in a reduce power consumption state comprises controlling, using a clock gating controller, the clock gating circuitry, responsive to the first condition, by passing clock signals to the receive path when programming the one or more receive path registers and thereafter not gate the clock signals to the receive path after programming the one or more receive path registers while waiting for valid echo signals return to the transducer if the transducer is in the imaging mode in which reprogramming of the one or more receive path registers for transmit and receive operations for successive beams is not needed. In one embodiment, the imaging mode includes reshooting of a line into an object to obtain a series of data for use in measuring changes in motion in the object on the line.

[0056] In one embodiment, placing one or both of the transmit and receive paths of an ultrasound transducer in a reduce power consumption state comprises controlling, using a clock gating controller, the clock gating circuitry, responsive to a first condition, by ignoring a first signal of the plurality of real-time signals indicating a start of the receive operation and maintaining gating of the clocks to the receive path after transmit beams have been transmitted from the transducer, the first condition indicating the transducer is in ping generation mode.

[0057] In one embodiment, placing one or both of the transmit and receive paths of an ultrasound transducer in a reduce power consumption state comprises controlling, using a clock gating controller, the clock gating circuitry, responsive to a first condition, by ignoring a first signal of the plurality of real-time signals indicating a start of the receive operation and maintain gating of the clocks to the receive path after register programming, the first condition indicating the transducer is in a mode in which one or more receive path registers are program yet no valid echo signal acquisition is to occur. In one embodiment, the mode relates to system initialization or a mode change.

[0058] In one embodiment, placing one or both of the transmit and receive paths of an ultrasound transducer in a reduce power consumption state using clock gating circuitry controlled by the one or more real-time signals comprises controlling the circuits to gate or pass clock signals without intervention of system software.

[0059] In one embodiment, the process further comprises controlling, using the clock gating controller, the circuits to pass clock signals to the receive path when programming the one or more receive path registers and thereafter not gate the clock signals to the receive path after programming the one or more receive path registers while waiting for valid echo signals return to the transducer if the transducer is in the imaging mode in which reprogramming of the one or more

receive path registers for transmit and receive operations for successive beams is not needed. In one embodiment, the imaging mode includes reshooting of a line into an object to obtain a series of data for use in measuring changes in motion in the object on the line.

[0060] In one embodiment, the plurality of real-time signals comprise: a first signal indicating a user has indicated a desire to freeze the image currently being display on a display of the ultrasound system (e.g., freeze signal **621**); a second signal indicating a start of a line (e.g., Start of Line signal **622**); a third signal indicating registers are being programmed (the registers being for the receive path) (e.g., programming registers signal **623**); a fourth signal indicating the receive path has been enabled to receive echoed acoustic signals (e.g., Receive_start signal **624**); and a fifth signal indicating an end of the line has been reached (e.g., End of Line signal **625**).

[0061] As discussed above, power reduction reduces component temperatures for increased reliability, eases the demands on the system power supplies which reduces cost and increases battery life, eliminates/reduces the need for active cooling systems which reduces cost, noise and complexity, simplifies software control, enables the design of smaller form factor products, and allows for the integration of additional electronics into sealed components such as the transducer handle.

[0062] Unless the context clearly requires otherwise, throughout the description and the claims, the words “comprise,” “comprising,” and the like are to be construed in an inclusive sense, as opposed to an exclusive or exhaustive sense; that is to say, in the sense of “including, but not limited to.” As used herein, the terms “connected,” “coupled,” or any variant thereof means any connection or coupling, either direct or indirect, between two or more elements; the coupling or connection between the elements can be physical, logical, or a combination thereof. Additionally, the words “herein,” “above,” “below,” and words of similar import, when used in this application, refer to this application as a whole and not to any particular portions of this application. Where the context permits, words in the above Detailed Description using the singular or plural number may also include the plural or singular number respectively. The word “or,” in reference to a list of two or more items, covers all of the following interpretations of the word: any of the items in the list, all of the items in the list, and any combination of the items in the list.

[0063] Some portions of the detailed descriptions above are presented in terms of algorithms and symbolic representations of operations on data bits within a computer memory. These algorithmic descriptions and representations are the means used by those skilled in the data processing arts to most effectively convey the substance of their work to others skilled in the art. An algorithm is here, and generally, conceived to be a self-consistent sequence of steps leading to a desired result. The steps are those requiring physical manipulations of physical quantities. Usually, though not necessarily, these quantities take the form of electrical or magnetic signals capable of being stored, transferred, combined, compared, and otherwise manipulated. It has proven convenient at times, principally for reasons of common usage, to refer to these signals as bits, values, elements, symbols, characters, terms, numbers, or the like.

[0064] It should be borne in mind, however, that all of these and similar terms are to be associated with the appro-

priate physical quantities and are merely convenient labels applied to these quantities. Unless specifically stated otherwise as apparent from the following discussion, it is appreciated that throughout the description, discussions utilizing terms such as “processing” or “computing” or “calculating” or “determining” or “displaying” or the like, refer to the action and processes of a computer system, or similar electronic computing device, that manipulates and transforms data represented as physical (electronic) quantities within the computer system’s registers and memories into other data similarly represented as physical quantities within the computer system memories or registers or other such information storage, transmission or display devices.

[0065] The present invention also relates to apparatus for performing the operations herein. This apparatus may be specially constructed for the required purposes, or it may comprise a general-purpose computer selectively activated or reconfigured by a computer program stored in the computer. Such a computer program may be stored in a computer readable storage medium, such as, but is not limited to, any type of disk including floppy disks, optical disks, CD-ROMs, and magnetic-optical disks, read-only memories (ROMs), random access memories (RAMs), EPROMs, EEPROMs, magnetic or optical cards, or any type of media suitable for storing electronic instructions, and each coupled to a computer system bus.

[0066] The algorithms and displays presented herein are not inherently related to any particular computer or other apparatus. Various general-purpose systems may be used with programs in accordance with the teachings herein, or it may prove convenient to construct more specialized apparatus to perform the required method steps. The required structure for a variety of these systems will appear from the description below. In addition, the present invention is not described with reference to any particular programming language. It will be appreciated that a variety of programming languages may be used to implement the teachings of the invention as described herein.

[0067] A machine-readable medium includes any mechanism for storing or transmitting information in a form readable by a machine (e.g., a computer). For example, a machine-readable medium includes read only memory (“ROM”); random access memory (“RAM”); magnetic disk storage media; optical storage media; flash memory devices; etc.

[0068] Whereas many alterations and modifications of the present invention will no doubt become apparent to a person of ordinary skill in the art after having read the foregoing description, it is to be understood that any particular embodiment shown and described by way of illustration is in no way intended to be considered limiting. Therefore, references to details of various embodiments are not intended to limit the scope of the claims which in themselves recite only those features regarded as essential to the invention.

We claim:

1. An ultrasound system for a dynamic power reduction comprising:

a memory; and

a processor coupled to the memory, wherein the processor is configured to:

determine subsystems including a first subsystem to be placed in a reduced power consumption state, the first subsystem including a transmit path having a transmitter to transmit acoustic signals;

and

determine, for the first subsystem a control subsystem to control clocking of the transmit path in response to at least one of a plurality of real-time signals that indicates a state of imaging operations performed by the transmit path, the control subsystem to provide one or more clocks to the transmit path to turn on the transmitter during a time interval while transmitting an acoustic signal based on the state indicated by the at least one of the plurality of real-time signals.

2. The ultrasound system of claim 1, wherein the processor is configured to:

identify registers for the first subsystem to be shut off at one or more times while the system is imaging.

3. The ultrasound system of claim 1, wherein the processor is configured to:

determine a first time associated with placing the first subsystem in the reduced power consumption state.

4. The ultrasound system of claim 1, wherein the processor is configured to:

determine one or more conditions associated with placing the first subsystem in the reduced power consumption state.

5. The ultrasound system of claim 1, wherein the processor is configured to:

identify one or more registers for the first subsystem that remain active at all times.

6. The ultrasound system of claim 1, wherein the processor is configured to:

identify one or more registers for the first subsystem to be placed into a sleep mode when the system is not imaging.

7. The ultrasound system of claim 1, wherein the processor is further configured to:

determine a second subsystem to be placed in the reduced power consumption state, the second subsystem including a receive path having a signal acquisition circuitry with a receiver to receive acoustic signals representing echoes, and wherein the control subsystem is to control clocking of the receive path in response to the at least one of the plurality of real-time signals that indicates a state of imaging operations performed by the receive path, the control subsystem to provide one or more clocks to the receive path to turn on the receiver while valid echo signals are expected to arrive at the receiver, wherein the control subsystem to provide the one or more clocks to the receive path during a first mode based on the state indicated by the at least one of the plurality of real-time signals.

8. The ultrasound system of claim 7, wherein the first mode is an imaging mode and includes generating successive transmit and receive beams using a transducer assembly of the system.

9. The ultrasound system of claim 1, wherein the control subsystem comprises:

a clock gating circuitry coupled to the transmit path and having circuits to gate clocks to the transmit path; and

a clock gating controller coupled to the clock gating circuitry to control the circuits to gate or pass clock signals to the transmit path.

10. The ultrasound system of claim 1, wherein the state indicates that the transmit path is expected to transmit the acoustic signal.

11. A non-transitory machine readable medium storing executable program instructions which when executed by a data processing system cause the data processing system to perform a method to dynamically reduce power for an ultrasound system, the method comprising:

determining subsystems including a first subsystem to be placed in a reduced power consumption state, the first subsystem including a transmit path having a transmitter to transmit acoustic signals;

and

determining, for the first subsystem a control subsystem to control clocking of the transmit path in response to at least one of a plurality of real-time signals that indicates a state of imaging operations performed by the transmit path, the control subsystem to provide one or more clocks to the transmit path to turn on the transmitter during a time interval while transmitting an acoustic signal based on the state indicated by the at least one of the plurality of real-time signals.

12. The non-transitory machine readable medium of claim 11, wherein the method further comprises:

monitoring the plurality of real-time signals;

and

placing the first subsystem in the reduced power consumption state using a clock gating circuitry controlled by the at least one of the plurality of real-time signals.

13. The non-transitory machine readable medium of claim 11, wherein the method further comprises:

identifying registers for the first subsystem to be shut off at one or more times while the system is in imaging.

14. The non-transitory machine readable medium of claim 11, wherein the method further comprises:

determining a first time associated with placing the first subsystem in the reduced power consumption state.

15. The non-transitory machine readable medium of claim 11, wherein the method further comprises:

determining one or more conditions associated with placing the first subsystem in the reduced power consumption state.

16. The non-transitory machine readable medium of claim 11, wherein the processor is configured to: identify one or more registers for the first subsystem that remain active at all times.

17. The non-transitory machine readable medium of claim 11, wherein the processor is configured to: identify one or more registers for the first subsystem to be placed into a sleep mode when the system is not imaging.

18. The non-transitory machine readable medium of claim 11, wherein the processor is further configured to:

determine a second subsystem to be placed in the reduced power consumption state, the second subsystem including a receive path having a signal acquisition circuitry with a receiver to receive acoustic signals representing echoes, and wherein the control subsystem is to control clocking of the receive path in response to the at least one of the plurality of real-time signals that indicates a state of imaging operations performed by the receive path, the control subsystem to provide one or more clocks to the receive path to turn on the receiver while valid echo signals are expected to arrive at the receiver, wherein the control subsystem to provide the one or more clocks to the receive path during a first mode based on the state indicated by the at least one of the plurality of real-time signals.

19. The non-transitory machine readable medium of claim 18, wherein the first mode is an imaging mode and includes generating successive transmit and receive beams using a transducer assembly of the system.

20. The non-transitory machine readable medium of claim 11, wherein the state indicates that the transmit path is expected to transmit the acoustic signal.
